and higher cardiac filling pressures lead to a reduction in cardiac output as described by the Starling curve. Low stroke volume further activates the sympathetic nervous system (SNS), which in turn worsens vasoconstriction, cardiac function, and renal perfusion. Excessive activation of both the RAS and SNS pathways has long been considered the hallmark of worsened CHF. However, other pathophysiologic mechanisms that could have important therapeutic implications have now been elucidated.

Adenosine Mediators Adenosine receptors are involved with tubuloglomerular feedback signaling and maintain intrarenal vascular tone through a number of complex pathways, which include A₁ receptors (A₁R), causing afferent arteriolar vasoconstriction, and A₂ receptors, inducing efferent vessel dilation. Actions of adenosine at the macula densa and mesangium depend on angiotensin, renin, nitric oxide, and prostaglandin levels. Mechanisms by which adenosine may also directly influence distal and collecting tubule transporters and vasopressin function are still under investigation. A₁R antagonists could thereby not only restore diuretic sensitivity but also allow appropriate aquaresis in severe CHF.

Venous Congestion Apart from low cardiac output, CHF frequently causes high right-sided pressures and venous congestion. High renal vein pressures combined with arterial hypoperfusion will narrow the arterial to venous pressure gradient and hydraulic forces and are thought to lower renal plasma flow and glomerular filtration rate (GFR).

Inflammatory Cytokines Chronic and acute exacerbations of CHF are associated with widespread inflammation and high levels of proinflammatory cytokines, such as tumor necrosis factor and interleukins 6 and 10. These are thought to contribute to the vicious circle that further boosts cardiac, renal, and other tissue dysfunction.

Anemia Anemia may be due to “chronic disease” or coexistent CKD. The importance of both recognizing and treating anemia has led to the term *cardiorenal anemia syndrome*, emphasizing this pharmacologically remediable aspect of CHF.

Diuretic Tolerance and Adverse Effects Many patients with CHF develop tolerance to chronic diuretic therapy, fail to have appropriate natriuresis despite escalating doses, and have worsening of neurohumoral mediator levels.³ Thus, some of the cardiac benefits of ACE inhibitors might be from blocking of diuretic-induced RAS activation. Consistent with this paradigm,

Classification of the Cardiorenal Syndrome
General definition: a pathophysiologic disorder of the heart and kidneys in which acute or chronic dysfunction in one organ may induce acute or chronic dysfunction in the other organ
Type I, Acute Cardiorenal Syndrome Abrupt worsening of cardiac function leading to acute kidney injury <i>Examples:</i> acute cardiogenic shock, acutely decompensated congestive heart failure
Type II, Chronic Cardiorenal Syndrome Chronic abnormalities in cardiac function leading to acute kidney injury <i>Example:</i> chronic congestive heart failure
Type III, Acute Renocardiac Syndrome Abrupt worsening of renal function causing acute cardiac disorder <i>Examples:</i> acute kidney ischemia, glomerulonephritis
Type IV, Chronic Renocardiac Syndrome Chronic kidney disease contributing to decreased cardiac function, cardiac hypertrophy, or increased risk of adverse cardiovascular events <i>Example:</i> chronic glomerular or interstitial disease
Type V, Secondary Cardiorenal Syndrome Systemic condition causing both cardiac and renal dysfunction <i>Examples:</i> diabetes mellitus, sepsis

Figure 71.1 Classification of the cardiorenal syndrome. (Modified with permission from reference 2.)

morbidity and mortality in advanced CHF increased up to four-fold with higher doses of diuretics despite the fact that there were no clinical or echocardiographic parameters to suggest that the high-dose group had any worse cardiac function.⁴ Similar conclusions were reached in the Management to Improve Survival in Congestive Heart Failure (MISCHF) study and the large ADHERE database. Finally, in a multicenter analysis, patients receiving high-dose diuretics had worsening of GFR compared with the control group on alternative medications, despite equivalent fluid losses.⁵

TREATMENT

General Approach and Limitations

A pragmatic approach for this challenging disorder (Fig. 71.2) is first to address potentially treatable problems, such as valvular disease, conduction disorders and arrhythmias, pericardial effusion, and coronary ischemia (e.g., by angioplasty and stenting). The clinician can then approximate the volume of excess fluid and craft a daily therapeutic goal concurrent with efforts to ensure compliance with salt restriction. Medication-naïve patients can then be cautiously treated as described in the following sections, with serial monitoring because hypotension or renal dysfunction commonly limits the use of pharmaceuticals. Determination of the degree to which a particular patient may be able to tolerate drug-induced hypotension (e.g., from afterload-reducing agents) is clinically challenging. Indeed, marked sensitivity of the blood pressure or renal function to low doses of RAS blockade should lead to a consideration of bilateral renal artery stenosis, a potentially remediable problem that can exacerbate the cardiorenal syndrome and also be a cause of flash pulmonary edema.

Figure 71.2 Stepwise treatment approach for decompensated CHF and the cardiorenal syndrome. ACE-I, angiotensin-converting enzyme inhibitors; ARBs, angiotensin receptor blockers; Hb, hemoglobin.

Stepwise Treatment Approach for Decompensated CHF and the Cardiorenal Syndrome
Step 1: Initial Evaluation 1. Compliance: Optimize adherence for medication regimen and salt restriction. 2. Electromechanical: Evaluate and treat arrhythmias and dyssynchrony 3. Anatomic, with imaging (cardiac catheterization, echocardiography) as appropriate for: a. Ischemia: angioplasty, stents, or surgery when appropriate for coronary artery stenoses b. Other remediable disorders, such as valvular heart disease, pericardial effusions, constrictive pericarditis 4. Anemia control: iron repletion, erythropoiesis-stimulating agents, or transfusions for Hb < 10 g/dl 5. Pharmacologic, with dose reductions for hypotension: Diuretics ACE inhibitors and ARBs Other agents: after load-reducing medications (i.e., hydralazine), digoxin
Step 2: For worsening renal function, ineffective diuresis, persistent CHF 1. Further pharmaceutical dose reductions to avoid hypotension 2. Re-evaluate for concurrent renal disease (i.e., renocardiac syndrome) a. Consider primary nephrologic disorders (i.e., parenchymal, obstruction) b. Consider evaluation for unilateral or bilateral renal artery stenosis
Step 3: For persistent hypotension, renal dysfunction, and CHF 1. Begin vasopressor (i.e., dobutamine) or consider ultrafiltration 2. Begin extracorporeal ultrafiltration, especially if patient is refractory to pressor: a. Intermittent slow ultrafiltration, when hypotension does not preclude adequate fluid removal during typically 4 to 6 hour sessions b. Continuous ultrafiltration, when equipment is available and patient becomes hypotensive or has worsening renal function with intermittent treatment sessions

Treatment Modalities for the Cardiorenal Syndrome	
Traditional	Diuretics: loop diuretics, long-acting thiazides Digoxin ACE-I and ARBs Vasodilators Blood transfusions
Recent Pharmaceuticals	Inotropes: milrinone, dobutamine Atrial natriuretic peptides Aquaretics: vasopressin antagonists Erythropoiesis-stimulating agents Adenosine receptor blockade
Mechanical	Biventricular pacing Ventricular assist devices
Ultrafiltration	Peritoneal dialysis Manual (CAPD) and automated using a cycler (APD) Extracorporeal therapies Intermittent short-duration ultrafiltration Slow continuous ultrafiltration

Figure 71.3 Treatment modalities for the cardiorenal syndrome. ACE-I, angiotensin-converting enzyme inhibitors; ARBs, angiotensin receptor blockers; CAPD, continuous ambulatory peritoneal dialysis; APD, automated peritoneal dialysis.

Pharmacologic Therapeutic Strategies

The pharmacologic management of CHF is summarized in Figure 71.3 and includes traditional cardiology approaches for arrhythmias (e.g., for atrial fibrillation) and afterload reduction. Use of inotropes is challenging in that there is limited efficacy from digoxin (other than rate control), and the intravenous agents (i.e., dobutamine and milrinone) are typically reserved for inpatients. An adequate diuresis by use of traditional medications in patients admitted with acute heart failure is not easily achieved; the ADHERE registry indicated that approximately 16% were discharged at a higher body weight. Specific pharmacologic strategies include the following.

Diuretics Despite the preceding concerns, some initially respond to escalating doses of diuretics. Loop diuretics need to be administered at frequent intervals in a high enough dose to achieve adequate drug levels within the glomerular filtrate. Coadministration of a long-acting thiazide diuretic can help maintain a natriuresis. In severe CHF, continuous low-dose infusion of a loop diuretic may be required.

RAS Antagonists ACE inhibitors and ARBs may worsen GFR in patients undergoing diuresis or those with advanced CKD, requiring temporary decrease in dose or withdrawal. Alternatively, diuretic dosage may need to be reduced before adjusting that of the ACE inhibitor. Hyperkalemia may also limit the use of RAS antagonists, including aldosterone antagonists.

Adenosine Antagonists It is hoped that by affecting tubuloglomerular feedback, A₁R antagonists could increase GFR, a benefit that theoretically could be partially offset by increased distal nephron workload and ischemia. In a pilot study, 300 patients with acute heart failure and renal dysfunction received the

selective A₁R antagonist rolofylline intravenously for 3 days.⁶ At days 14 and 60, some treatment benefits in dyspnea, smaller rises in serum creatinine levels, mortality, and readmission rates were noted. On the basis of these results, the 2000-patient PROTECT trial is ongoing.

Erythropoiesis-Stimulating Agents In a large registry, 25% of CHF individuals were moderately to severely anemic (hemoglobin 5 to 10.7 g/dl), and anemia (hemoglobin <12.1 g/dl) was associated with higher in-hospital mortality, longer length of stay, and more readmissions at 90 days.⁷ Improvements in anemia and cardiac function may also benefit GFR. In small patient series, correction of severe anemia (hemoglobin <10 g/dl) improved CHF and clinical outcomes. Prospective multicenter trials to test whether further benefit can be achieved from normalization of hemoglobin values in CHF are ongoing. Until such data are available, we believe the most prudent course is to follow renal disease targets (see Chapter 79).

Antidiuretic Hormone Antagonists Release of vasopressin by (nonosmotic) low cardiac output results in water retention and hyponatremia. In clinical trials, V₂-selective antagonists such as tolvaptan and lixivaptan or a nonselective oral V_{1A}/V₂ antagonist indeed increased urine output and serum sodium, but it has not yet been proved that this results in clinically relevant improvement in CHF. Treatment of 537 patients for a minimum of 60 days had no effect at 10 months on all-cause mortality or heart failure–related morbidity.⁸

Natriuretic Peptides Early clinical trials were encouraging for a cardiac benefit, but there was no improvement in renal function. These agents should no longer be used for CHF because of subsequent data demonstrating increased short-term mortality in such patients.⁹

Nonrenal Salt and Water Removal

Nonrenal methods of salt and water removal are advantageous because they avoid tubuloglomerular feedback–mediated neurohumoral pathway activation and are effective in patients refractory to pharmaceutical treatment.

Paracentesis

In a small study of five patients, removal of approximately 3 liters of ascites resulted in a decrease in intra-abdominal pressure and improved renal function.¹⁰ Repeated intermittent paracentesis, however, causes significant protein losses, often the need for albumin repletion, and the possibility of subsequent fluid leakage or infection. Nevertheless, the role for this approach in select patients needs to be better defined, especially in those settings in which the more elaborate and costly nonpharmacologic methodologies are not available.

Ultrafiltration: Peritoneal Dialysis

The techniques and potential complications of peritoneal dialysis (PD) are described in Chapters 92 and 93, but there are specific issues in regard to its use for CHF. The rapid use of PD catheters for acute CHF patients increases the risk of early fluid leaks and peritoneal infection. PD-induced electrolyte disturbances may worsen rhythm control. Large peritoneal fluid volumes can potentially compromise respiration that might already be tenuous in CHF, which could be avoided by frequent lower volume exchanges through automated cyclers.

Early small case series highlighted the safety of catheter placement and efficacy of outpatient PD for fluid removal in CHF patients. Intermittent PD accomplished ultrafiltration (UF) and also restored diuretic sensitivity. In one of the larger uncontrolled investigations,¹¹ 20 patients with severe CHF were treated with automated PD for 8 hours thrice weekly, achieving UF of 2.1 ± 0.5 l/session. At 1-year follow-up, there were improvements in echocardiographic measures of cardiac contractility, NYHA class, and hospitalization days; but some of the benefit may have been from resolving salt and fluid excesses due to concurrent CKD. Improvements in cardiac parameters were similarly described in 15 CHF patients.¹² This study, however, noted a high rate of complications, and 16% of the patients had peritoneal or abdominal wall infections, difficulty with dialysate effluent drainage, or displaced catheters requiring replacement.

A number of review articles have attempted to reconcile the diverse published dialysis protocols.¹³ These support the efficacy of PD in cardiorenal (apart from renocardiac) patients for fluid removal, better NYHA class,¹² bridging to cardiac transplantation, decrease in hospitalization days, and improved quality of life.

Ultrafiltration: Conventional Hemodialysis or Hemofiltration

There is extensive experience with intermittent hemodialysis techniques for fluid removal in CHF. Traditionally, acute temporary or tunneled dual-lumen catheters are inserted (see Chapter 87). Permanent access is often precluded from a cardiac standpoint because these arteriovenous fistulas or grafts may shunt a liter or more of blood per minute. When the intention is to provide UF only, no dialysate is used ("isolated UF"; see Chapter 89); however, when electrolyte disorders are already present, they can be slowly corrected by temporary use of traditional dialysis techniques. The major risk from UF is hemodynamic instability due to excess fluid removal. Even with careful setting of the UF rate, many unstable CHF patients will not tolerate removal of 2 liters or more during typical 2- to 4-hour treatment times. Importantly, episodes of hypotension not only will prevent further fluid removal but also can induce acute kidney injury and potentially make the patient dialysis dependent.

It is believed that the key to hemodynamic stability is to dramatically slow the UF rate to allow adequate refill of the vascular space (see later), and this approach led to longer and then continuous treatment modalities: slow extended-duration isolated UF and continuous venovenous hemofiltration. There are multiple case reports and small series of patients treated with such techniques, but most had heterogeneous patient populations and lacked appropriate control groups, well-defined outcome measures, or strict treatment protocols.

Ultrafiltration: Recent Advances in Extracorporeal Techniques

Widespread use of these modalities so far has been limited by the logistic hurdles of performing them outside of an ICU setting. The barriers of extended treatment times and the need for 1:1 supervision by nurses have been overcome with commercially available modern devices dedicated to isolated UF. These now have small extracorporeal blood volumes (<100 ml) and allow blood flows low enough (<50 ml/min) to permit use of temporary peripheral vein catheters; they have pre-prepared tubing for one-step loading, computerized simple user interfaces with embedded help screens, remote monitoring capabilities, and miniaturization for portability. Treatment times range from

6 hours a day to continuous during multiple days. One such compact UF-dedicated device for use outside of the ICU setting has been extensively tested.

The first feasibility study¹⁴ demonstrated that 16- to 18-gauge catheters could deliver blood at up to 40 ml/min and resulted in 2611 ± 1002 ml (up to 3725 ml) of UF during approximately 7 hours. In another study¹⁵ of 20 patients with decompensated CHF and serum creatinine levels of at least 1.5 mg/dl or diuretic resistance, the UF rate was as high as 500 ml/h (decreased to 200 ml/h if hypotension occurred), and the therapy was continued until the CHF symptoms resolved. With more than 8 liters of fluid removal, patients were discharged in just 3.7 days without changes in their serum urea or creatinine values and had improved heart failure scores; seven had resolution of hyponatremia, and subjects appeared to have a decreased rate of readmission. Finally, in the prospective UNLOAD trial, 200 CHF patients were randomized to early UF or intravenous diuretics and observed for 90 days.¹⁶ The UF achieved by the study was 241 ml/h for 12.3 ± 12 hours, which led to a weight reduction of 5.0 ± 3.1 kg during the 2 days. This was approximately 2 kg more than for those in the control diuretic group. Although dyspnea was improved in those undergoing UF at 8 hours, that score was no different at 48 hours. The groups were statistically similar for rises in serum creatinine of more than 0.3 mg/dl, blood urea nitrogen and sodium levels, heart failure scores, episodes of hypotension, and hospitalization length of stay. At 90 days, the UF group exhibited fewer total rehospitalizations (18% versus 32%), rehospitalization days (1.4 versus 3.8 days), and unscheduled office and emergency department visits (21% versus 44%). Potential weaknesses of the study design included sponsorship by the manufacturer, submaximal medical therapy in the diuretic group, and uncertainties as to post-hospitalization care and readmission. Last, there are small case series of patients who underwent long-term UF treatments for up to approximately a year and reportedly had sustained CHF benefits.

The Effect of Ultrafiltration on the Pathophysiology of Congestive Heart Failure

In 24 patients with refractory CHF, removal of up to 4 liters of fluid in a few hours¹⁷ did not affect plasma volume, thereby confirming the matching of UF and plasma refill rate. Even at 24 hours after the procedure, the patients had reduced right atrial, pulmonary artery, and wedge pressures; increased stroke volume; stable heart rates and systemic vascular resistance; and improved responsiveness to diuretics.

UF in CHF patients decreases levels of norepinephrine, aldosterone, and renin.¹⁸ UF also reduced systemic levels of inflammatory cytokines, a phenomenon that was not observed in patients treated with just diuretics. Some patients reportedly also have improved exercise capacity and pulmonary function. Last, in comparing UF with diuretics, it is important to appreciate that salt losses vary between these therapies. Part of the benefit from UF may be due to the convection of isotonic fluid, compared with less removal of sodium in the diuretic-induced hypotonic urine.

The Effect of Ultrafiltration on Renal Function

Benefits of UF for renal function appear to occur predominantly in patients with low baseline urine output (<1 l/day); UF reverses the RAS and SNS activation, thereby improving renal perfusion and GFR and restoring sensitivity to diuretics.¹⁹ In contrast, in

CHF patients with a mean baseline GFR of 48 ml/min and preserved diuretic sensitivity, there were no significant differences in the kidney parameters before or after 2 days of either UF or intravenous diuretic therapy.²⁰

There are thus encouraging but not unanimous reports of improving renal function with UF compared with diuretics, but it is important that cautious fluid removal can be accomplished without harming the kidney. Multiple studies have demonstrated that patients can undergo extracorporeal UF without a significant rise in serum creatinine or detriment to renal hemodynamics.^{15,16} Determination of a safe rate of UF can be difficult, however, and excessive fluid removal can unquestionably lead to kidney injury. In a 25-patient retrospective study²¹ of relatively high volume UF compared with usual care, the fluid removal rate was 325 ± 117 ml/h for 37 ± 25 hours. This resulted in greater weight reduction than in the historical control group but was associated with more patients having a rise in serum creatinine of more than 0.5 mg/dl (44% versus $\leq 24\%$). This led the investigators to alter their treatment protocol so that the rate of UF would be reduced to 100 to 200 ml/h.

Ultrafiltration: Setting the Rate of Fluid Removal

The key concept is to avoid intravascular fluid depletion by ensuring that the UF rate does not exceed the rate at which the vascular plasma compartment is being refilled from interstitial spaces. The plasma refill rate can vary during the course of fluid removal, as it is dependent on Starling forces (generated by the plasma oncotic pressure and the gradient between interstitial and vascular hydrostatic pressures) and the permeability of vascular basement membranes. If the UF rate exceeds the plasma refill rate, hemoconcentration, hypovolemia, hypotension, and decreased renal function develop. Equipment has been developed for hemodialysis machines that optically monitors hemoconcentration, and this approach can also be used as a guide for UF in patients with refractory CHF. So far, body fluid determination by bioimpedance vector analysis (see Chapter 90) has had little application in cardiology, despite being a validated important tool in nephrology.

Safety and Risks of Extracorporeal Therapies

Whereas newer simplified devices for isolated UF have improved the ease of patient care, these modalities are not risk free. In a small outpatient 1-year study, two deaths of 14 patients were attributed to complications of the UF.²² In the larger UNLOAD trial,¹⁶ however, the UF therapy proved very safe, without increased mortality or hemorrhage compared with those undergoing standard care. It is hoped that newer machines dedicated to isolated UF will have an added margin of safety conferred by low rates of filtration and blood flow as well as more robust automated monitoring software. Nevertheless, all complications that can occur in hemodialysis therapies are of course also relevant for CHF patients receiving isolated UF (see Chapter 91).

Hepatorenal Syndrome

Ignatius K.P. Cheng, Felix F.K. Li

DEFINITION

Hepatorenal syndrome (HRS) is a reversible and functional renal failure that occurs in patients with acute or chronic liver disease, advanced hepatic failure, and portal hypertension. It is characterized by impaired renal function and marked abnormalities in the arterial circulation and endogenous vasoactive systems. In the kidney, there is pronounced vasoconstriction resulting in low glomerular filtration rate (GFR). In the splanchnic circulation, there is a predominance of arteriolar vasodilation resulting in reduction of systemic vascular resistance and arterial hypotension.^{1,2} Two forms of HRS can be identified on the basis of the progression of the disease (Fig. 72.1). An acute form (type 1) is characterized by a rapid deterioration in renal function, whereas a chronic form (type 2) is marked by an insidious onset and a slowly progressive course.

Pseudohepatorenal Syndrome

Pseudohepatorenal syndrome describes concurrent hepatic and renal dysfunction secondary to a wide variety of infectious, systemic, circulatory, genetic, and other diseases and after exposure to a variety of drugs and toxins. In these conditions, the liver does not play an etiologic role in the pathogenesis of renal failure, and they must be excluded before the diagnosis of HRS can be established.

PATHOPHYSIOLOGY AND PATHOGENESIS

Renal and Systemic Hemodynamic Changes

In HRS, reduction in GFR occurs mainly as a result of renal cortical hypoperfusion after intense cortical renal vasoconstriction, which can be demonstrated angiographically as marked beading and tortuosity of the interlobular and proximal arcuate arteries and the absence of a distinct cortical nephrogram and vascular filling of the cortical vessels (Fig. 72.2).³ Intense renal vasoconstriction occurs in the presence of splanchnic vasodilation, which gives rise to a low peripheral vascular resistance and a low systemic mean arterial blood pressure (MAP). This further compromises renal perfusion because intense renal vasoconstriction results in blunting of the autoregulation of renal blood flow, so that renal perfusion becomes more pressure dependent. In HRS, filtration fraction is also reduced, reflecting a dominant increase in afferent arteriolar tone and a decrease in the ultrafiltration coefficient. Serial systemic hemodynamic studies showed that HRS occurs in the setting of reduced MAP, cardiac output,

and wedge pulmonary pressure without change of systemic vascular resistance. These findings suggest that the inability of the heart to increase its output to compensate for a decrease in cardiac preload also significantly contributes to the pathogenesis of HRS.⁴ Vasoconstriction is not confined to the renal vascular bed, and in type 1 HRS in particular, it is also observed in the vasculature of other organs, including the liver, brain, muscle, and skin.²

Neurohumoral Abnormalities

The renal and systemic hemodynamic changes that characterize HRS are a direct consequence of neurohumoral disturbances.² The sympathetic nervous system is activated, and the sympathetic discharges through the renal nerves are markedly increased. Increases in the plasma and urinary levels of vasoconstrictors and in the plasma level of vasodilators are observed in patients suffering from HRS. The vasoconstrictors include plasma renin activity, norepinephrine, neuropeptide Y, arginine vasopressin, endothelin and F₂ isoprostanes, and urinary cysteinyl leukotrienes; the vasodilators include plasma endotoxin, nitrite and nitrate (end product of nitric oxide metabolism), and glucagon. Activation of the vasoconstrictor systems is thought to be the cause of renal vasoconstriction; activation of the vasodilator systems is thought to occur mainly in the splanchnic circulation and to lead to splanchnic vasodilation.

Most of these neurohumoral abnormalities found in HRS are also detected, albeit to a lesser extent, in decompensated cirrhosis (with ascites) with normal renal function and in compensated cirrhosis (without ascites). These findings support the hypothesis that HRS most likely represents one end of the spectrum of homeostatic abnormalities that occur in liver failure and portal hypertension.

In contrast to increased plasma and urinary levels of vasoconstrictors and plasma level of vasodilators, decreased levels of urinary vasodilators have been observed in HRS. These include prostaglandin E₂, 6-keto-prostaglandin F₁ (a stable metabolite of renal prostacyclin), and kallikrein. As the level of these urinary vasodilators is normal in compensated cirrhosis and higher than normal in decompensated cirrhosis with ascites and normal renal function, it is postulated that a reduction of renal vasodilators is the final event that leads to the development of HRS.

Summary of Pathogenetic Events

Figure 72.3 is a simplified diagram of the pathogenetic events that lead to HRS. Liver failure and portal hypertension through

Definition of Hepatorenal Syndrome Type 1 and Type 2
Type 1 Hepatorenal Syndrome
Doubling of serum creatinine >2.5 mg/dl ($220 \mu\text{mol/l}$) or a 50% reduction in 24-hr creatinine clearance to <20 ml/min <2 weeks
Frequently follows a precipitating event (e.g. infection)
Median survival without treatment: 2 weeks
Type 2 Hepatorenal Syndrome
Less rapid renal functional deterioration than type 1
Mainly presents with refractory ascites
Median survival without treatment: 4–6 months

Figure 72.1 Definition of hepatorenal syndrome type 1 and type 2.

endotoxemia and increased shear stress increase vascular production of vasodilators, including nitric oxide and glucagon in the splanchnic circulation, leading to the initiating event of splanchnic arteriolar vasodilation (the peripheral arterial vasodilation hypothesis). Splanchnic vasodilation leads to a decrease in systemic vascular resistance, but MAP is initially maintained by an increase in cardiac output, resulting in a hyperdynamic circulation. Splanchnic vasodilation also decreases arterial filling and reduces the effective arterial blood volume. The subsequent stimulation of the central volume receptors leads to compensatory activation of the vasoconstrictor systems, in particular the arginine vasopressin system, renin-angiotensin-aldosterone system (RAAS), and sympathetic nervous system (including its hormones norepinephrine and neuropeptide Y), which help restore effective arterial blood volume. This restoration is achieved in patients with compensated cirrhosis but not in patients with decompensated cirrhosis, in whom progressive splanchnic arteriolar vasodilation leads to increased splanchnic capillary pressure, resulting in an increase in lymph formation that exceeds reabsorption capacity. In parallel, further contraction of the effective arterial blood volume leads to reduction of systemic MAP and further stimulation of the vasoconstrictor systems, resulting in sodium and water retention. The net result of these combined effects is continuous ascites formation (the forward theory of ascites formation).

As the splanchnic circulation is resistant to the effects of vasoconstrictors because of local release of vasodilators, progressive splanchnic vasodilation continues to occur as liver failure and portal hypertension progress. This leads to continued contraction of effective arterial blood volume, which, in combination with the progressive inability of the cirrhotic heart to respond to reduced preload consequent to splanchnic vasodilation, results in further reduction of MAP and more intense stimulation of the vasoconstrictor systems. Normally, the effect of vasoconstrictors on the renal circulation is counterbalanced by the reactive production of intrarenal vasodilators. It is postulated that HRS develops when the balance of activities between the renal vasoconstrictors and intrarenal vasodilators finally breaks down. The likelihood that this will occur increases with progressive or acute deterioration in liver function or increasing severity of portal hypertension (e.g., after acute alcoholic hepatitis) and is precipitated by events that lead to further volume contraction and reduction of the effective arterial blood volume (see later discussion).

Figure 72.2 Hepatorenal syndrome (HRS). **A**, Renal angiogram (the arrow marks the edge of the kidney). **B**, The angiogram carried out in the same kidney at autopsy. Note complete filling of the renal arterial system throughout the vascular bed to the periphery of the cortex. The vascular attenuation and tortuosity seen previously (**A**) are no longer present. The vessels are also histologically normal. This indicates the functional nature of the vascular abnormality in HRS.³

EPIDEMIOLOGY

The possibility for development of HRS in the cirrhotic patient is estimated at 18% at 1 year and 39% at 5 years.⁵ Neither the etiology nor the Child-Pugh score (<http://homepage.mac.com/sbolland/contrivances/childpugh.html>) predicts the incidence of HRS. Rather, independent predictors of HRS include low serum sodium concentration, high serum renin activity,^{4,5} absence of hepatomegaly,⁵ abnormal renal duplex Doppler ultrasound study (resistive index >0.7),⁶ and low cardiac output.⁴

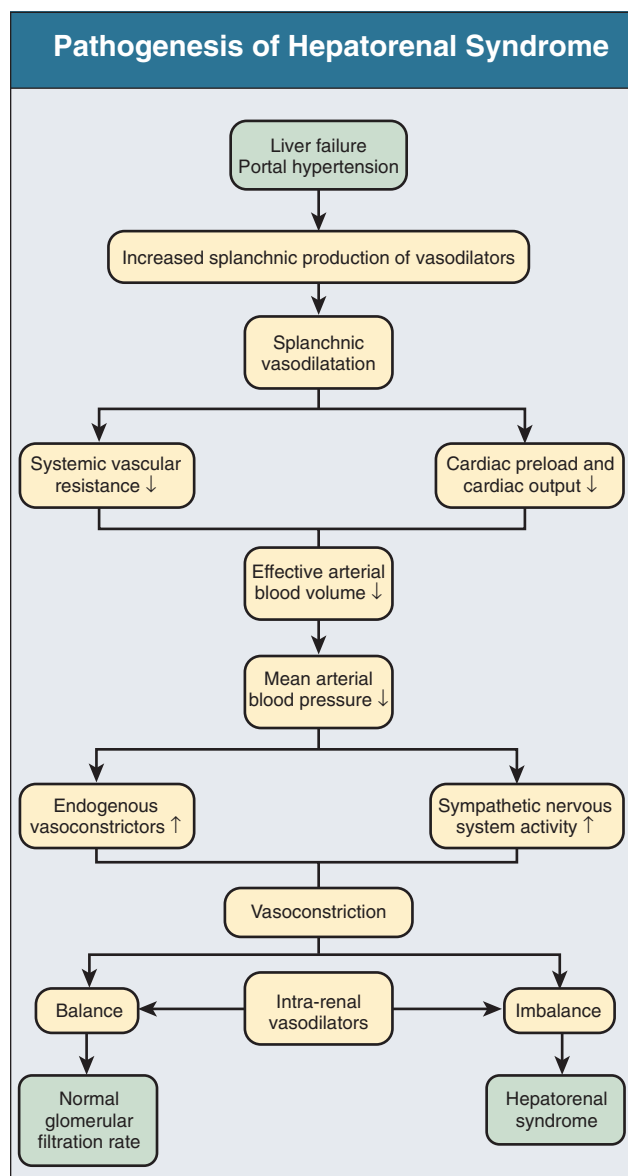

Figure 72.3 The pathogenesis of hepatorenal syndrome.

CLINICAL MANIFESTATIONS

Type 1 and type 2 HRS are considered to be different syndromes rather than different expressions of a common underlying disorder.² Type 1 HRS is characterized by a rapid decline in renal function and is most often observed in patients suffering from acute liver failure, acute alcoholic hepatitis, or acute decompensation on a background of cirrhosis (see Fig. 72.1). This group of patients, apart from suffering from rapidly progressive renal failure, also suffers from multiorgan dysfunction including severe hepatic failure (severe hyperbilirubinemia, prolongation of prothrombin time), hepatic encephalopathy, and relative adrenal insufficiency. Hyponatremia is almost always present, and arterial blood pressure is usually low. Acute decompensation in type 1 HRS may be precipitated by bacterial infections (especially spontaneous bacterial peritonitis), gastrointestinal bleeding, vigorous diuretic therapy, abdominal paracentesis, or the administration of substances such as nonsteroidal anti-inflammatory drugs (NSAIDs) that further suppress intrarenal generation of

vasodilators (e.g., prostaglandins). Left untreated, it tends to run a rapid and progressive downhill course, resulting in death of the patient within weeks.⁵

Type 2 HRS is characterized by insidious onset and slowly progressive deterioration of renal function. This is most often observed in patients with decompensated cirrhosis and portal hypertension. This group of patients tends to be less severely jaundiced and mainly presents with refractory ascites. Low-normal arterial blood pressure, modest prolongation of prothrombin time, and hyponatremia are usually present. It tends to run a slowly progressive downhill course during months and most likely reflects the natural course of the disease because additional precipitating factors are not usually identified.^{2,5}

PATHOLOGY

HRS is, by definition, a functional renal disorder, and the presence of significant glomerular and tubular disease excludes the diagnosis. However, glomerular abnormalities, including mesangial expansion, capillary wall thickening, mesangial and capillary wall electron-dense deposits, and immune deposits of C3 and the immunoglobulins IgA, IgM, and IgG, are frequently found in cirrhotic patients with normal renal function and minimal urinary abnormalities. The presence of such glomerular abnormalities in a cirrhotic patient, therefore, does not exclude the diagnosis of HRS. Protrusion of the proximal tubular epithelium into Bowman's space (glomerulotubular reflux) is not specific for HRS and is found in other conditions associated with profound renal ischemia and terminal hypotension. Although early autopsy studies demonstrated normal tubular morphology in patients dying of HRS, detailed light and electron microscopic studies have documented proximal tubular lesions consistent with ischemic injury.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnostic criteria for HRS were established by the International Ascites Club¹ in 1996 (Fig. 72.4) and have recently been revised (Fig. 72.5).⁷ The main differences between the new and old criteria include the exclusion of creatinine clearance as a measure of renal function because of the difficulty in obtaining an accurate urine collection, the removal of ongoing bacterial infection as an exclusion criterion so that treatment of HRS is not delayed in these patients, the substitution of albumin for saline as the preferred fluid for plasma volume expansion, and the removal of the minor criteria as they are not thought to be essential.

The diagnosis of HRS is mainly one of exclusion and should be suspected in any patient with acute or chronic liver disease with advanced liver failure and portal hypertension who develops progressive renal impairment. There may be significant renal impairment despite a normal serum creatinine or blood urea nitrogen concentration because these patients are frequently malnourished, with reduced lean body mass, and often have a low urea generation rate because of liver failure and low protein intake. Severe hyperbilirubinemia, which is often present in patients with HRS, interferes with the Jaffe reaction for creatinine quantification and may cause falsely low results. Enzymatic creatinine assays are less susceptible to high bilirubin levels. In cases of uncertainty, GFR may be assessed with use of serum cystatin C, ¹²⁵I-iothalamate, ⁵¹Cr-labeled EDTA, or inulin clearance.⁸

Pseudohepatorenal syndrome (Fig. 72.6)⁹ is usually easy to exclude because the etiologic agent is frequently known and both

Diagnostic Criteria for Hepatorenal Syndrome	
Major Criteria	
Chronic or acute liver disease with advanced hepatic failure and portal hypertension	
Low glomerular filtration rate, as indicated by serum creatinine >1.5 mg/dl (135 μ mol/l) or 24-hr creatinine clearance <40 ml/min	
Absence of shock, ongoing bacterial infection, and current or recent treatment with nephrotoxic drugs	
Absence of gastrointestinal fluid losses (repeated vomiting or intense diarrhea)	
Absence of renal fluid losses (weight loss >500 g/day for several days in patients with ascites without peripheral edema or 1000 g/day in patients with peripheral edema)	
No sustained improvement in renal function (decrease in serum creatinine to 1.5 mg/dl [135 μ mol/l] or less or increase in creatinine clearance to 40 ml/min or more) following diuretic withdrawal and expansion of plasma volume with 1.5 liters of isotonic saline	
Proteinuria <500 mg/day and no ultrasonographic evidence of obstructive uropathy or parenchymal renal disease	
Additional Criteria	
Urine volume <500 ml/day	
Urine sodium <10 mmol/l	
Urine osmolality greater than plasma osmolality	
Urine red blood cells <50 per high-power field	
Serum sodium concentration <130 mmol/l	

Figure 72.4 Diagnostic criteria for hepatorenal syndrome. (Modified from reference 1.)

Revised Diagnostic Criteria for Hepatorenal Syndrome	
Cirrhosis with ascites	
Serum creatinine > 1.5 mg/dl (133 μ mol/l)	
No improvement in serum creatinine (decrease to a level of 1.5 mg/dl) after at least 2 days with diuretic withdrawal and volume expansion with albumin. The recommended dose of albumin is 1 gm/kg of body weight per day up to a maximum of 100 gm/day.	
Absence of shock	
No current or recent treatment with nephrotoxic drugs	
Absence of parenchymal kidney disease as indicated by proteinuria >500 mg/day, microhaematuria (>50 red blood cells per high power field) and/or abnormal renal ultrasound	

Figure 72.5 Revised diagnostic criteria for hepatorenal syndrome. (Modified from reference 7.)

renal and liver functional abnormalities are often found at first clinical presentation, when there is no evidence of advanced liver failure and portal hypertension. In contrast, HRS invariably occurs after liver failure and portal hypertension are fully established and frequently develops when the patient is undergoing treatment of these conditions or their complications.

In patients with preexisting liver failure and portal hypertension, nephrotoxic agents (e.g., NSAIDs and aminoglycosides) must be stopped, and conditions leading to renal failure must be excluded by careful history, physical examination, urine examination, and ultrasound study before the diagnosis of HRS can be considered. The absence of shock, gastrointestinal bleeding, and

Causes of Pseudohepatorenal Syndrome		
Potential Causes	Predominantly Tubulointerstitial Involvement	Predominantly Glomerular Involvement
Infections	Sepsis, leptospirosis, brucellosis, tuberculosis, Epstein-Barr virus, hepatitis A virus	Hepatitis B and C viruses, HIV infection, <i>Schistosoma mansoni</i> , liver abscess
Drugs	Tetracycline, rifampin (rifampicin), sulfonamide, phenytoin, allopurinol, fluroxene, methotrexate (high dose), acetaminophen (overdose)	
Toxins	Carbon tetrachloride, trichloroethylene, chloroform, elemental phosphorus, arsenic, copper, chromium, barium, amatoxins,* raw carp bile toxins†	
Systemic disease	Sarcoidosis, Sjögren's syndrome	Systemic lupus erythematosus, vasculitis, cryoglobulinemia, amyloidosis
Circulatory failure	Hypovolemic or cardiogenic shock	
Malignancy	Lymphoma, leukemia	
Congenital and genetic disorders	Polycystic liver and kidney disease, nephronopthisis and congenital hepatic fibrosis	
Miscellaneous	Fatty liver of pregnancy, Reye's syndrome	Eclampsia, HELLP syndrome, cirrhotic glomerulopathy

Figure 72.6 Causes of pseudohepatorenal syndrome. *Accidental poisoning after ingestion of mushrooms of the *Amanita* genus. †Accidental poisoning after ingestion of the raw gallbladder or bile of the grass carp (a common practice in rural East Asia). (Modified from reference 9.)

excess gastrointestinal, peritoneal, or renal fluid loss must also be documented. Prerenal acute renal failure must be excluded by withdrawal of diuretics and fluid challenge either with 1.5 liters of normal saline or preferably with albumin, 1 g/kg of body weight per day up to the maximum of 100 g/day for 2 days. Fewer than 50 urinary red blood cells per high-power field and urinary protein of less than 500 mg/l help exclude significant coexisting glomerular or tubulointerstitial disease leading to renal failure and support the diagnosis of HRS.

NATURAL HISTORY

The prognosis of HRS is poor. Without treatment, the median survival rate for type 1 HRS is about 2 weeks; that of type 2 HRS is about 4 to 6 months.⁵ Recovery of renal function coincides with recovery of liver function and liver regeneration and follows therapeutic intervention. Renal failure is infrequently an immediate cause of death, and most patients succumb to the other complications of liver failure and portal hypertension, such as hepatic encephalopathy, gastrointestinal bleeding, and sepsis. Despite this, renal failure refractory to therapy is an important determinant of outcome.

TREATMENT

Preventive Measures

Accepting the hypothesis that HRS represents one end of the spectrum of the homeostatic abnormalities in liver failure and portal hypertension and is precipitated by such events as volume contraction, sepsis, and the administration of potential nephrotoxic agents, it follows that a major focus of treatment must be to avoid the occurrence of such events and to treat them promptly when they occur. In patients with decompensated liver disease, the common events that lead to volume contraction include gastrointestinal bleeding, injudicious use of lactulose (for treatment of hepatic encephalopathy) resulting in profuse diarrhea, and excessive diuretic therapy or paracentesis for the treatment of ascites. To avoid the last, a stepwise approach to the treatment of ascites is recommended. All patients are advised to have bed rest and to follow a low-sodium diet (60 to 90 mmol/day, equivalent to about 1.5 to 2 g of salt per day). After this, spironolactone is prescribed at increasing doses (100 mg/day as initial dosages; if there is no response within 4 days, 200 mg/day; if no further response, 400 mg/day). When there is no response to the highest dose of spironolactone, furosemide is added at increasing dosages every 2 days (40 to 160 mg/day). In cases of diuretic resistance, therapeutic paracentesis, when it is combined with plasma volume expansion using albumin (8 g per liter of ascites removed), is helpful and is associated with a low incidence of circulatory dysfunction after treatment. The use of potentially nephrotoxic agents, including angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, NSAIDs, aminoglycosides, and radiocontrast media, should be avoided as far as possible. Therapeutic agents (e.g., β -blockers and somatostatin) that are employed for the treatment of bleeding esophageal and gastric varices reduce GFR, and their use must be monitored carefully. There should be a low threshold for antibiotic therapy for suspected sepsis. Spontaneous bacterial peritonitis must be excluded by regular examination of ascites fluid and treated not only with broad-spectrum antibiotics but also with albumin infusion (1.5 g/kg initially and 1 g/kg 2 days later) because the latter has been shown to prevent the subsequent development of HRS.¹⁰ Primary prophylaxis of spontaneous bacterial peritonitis with norfloxacin has recently been shown not only to prevent its development but also to delay the development of HRS and to improve patient survival in cirrhotic patients at high risk for complications (low ascitic protein level <15 g/L, advanced liver failure with Child-Pugh score ≥ 9 and serum bilirubin ≥ 3 mg/dL, or impaired renal function with serum creatinine ≥ 1.2 mg/dL or serum sodium ≤ 130 mmol/L).¹¹ Norfloxacin is thought to exert its renoprotective effect by reducing bacterial translocation from the intestine, endotoxemia, and nitric oxide generation, which in turn leads to improved hemodynamics. Prophylactic use of pentoxifylline (400 mg orally three times per day) also prevents the development of HRS in patients suffering from acute alcoholic hepatitis, probably by inhibiting the synthesis of tumor necrosis factor α .¹²

General Approach to Treatment

Once the diagnosis of HRS is made, patients should be assessed for orthotopic liver transplantation (OLT). Suitable candidates, especially those suffering from type 1 HRS, should be placed on the urgent waiting list for cadaveric or living donor liver transplantation. In patients who are transplantation candidates but do not yet have a donor, bridge treatments to OLT include

Pharmacotherapies for Hepatorenal Syndrome

*Terlipressin, IV 0.5–1 mg q4–6 h to start, doubling every 2 days up to a maximum of 12 mg/day if serum creatinine decreases < 25% after 2 days. Maximum duration of treatment 14 days

Vasopressin, 0.01 U/min to start and titrating the dose upwards to a maximum of 0.8 U/min to achieve an increase of MAP of at least 10 mmHg. Maximum duration of treatment 11 days

Norepinephrine, IV 0.5 mg/h to start, increasing dose by 0.25 to 0.5 mg/h every 4 hours up to maximum of 3 mg/h to achieve an increase of MAP of at least 10 mmHg. Maximum duration of treatment 15 days

Midodrine, oral 7.5 mg tid + Octreotide SC 100 μ g tid to start, increasing midodrine dose to maximum of 12.5–15 mg tid and octreotide dose to maximum of 200 μ g tid to achieve an increase of MAP of at least 15 mmHg. Maximum duration of treatment not defined

Figure 72.7 Pharmacotherapies for hepatorenal syndrome. All patients should also receive albumin, 1 g/kg up to 100 g in the first day and 20 to 40 g/day afterward. Central venous pressure monitoring to achieve a reading of 10 to 15 mm Hg is desirable but not mandatory. *Terlipressin is the preferred treatment. MAP, mean arterial blood pressure. (Modified from references 7 and 24.)

pharmacotherapy, mechanical shunt, extracorporeal liver support therapy, and, in patients with advanced uremia, renal replacement therapy. In some patients who are not transplantation candidates, prolonged survival in terms of months may still be achievable with some of these therapies.

Pharmacotherapy

At present, the most promising pharmacotherapy appears to be vasoconstrictor therapy targeted at reversal of splanchnic arteriolar vasodilation and restoration of the effective arterial blood volume with use of albumin (Fig. 72.7). Vasodilator therapy, which aims at reversal of renal vasoconstriction, is limited by profound hypotension because activation of the vasoconstrictor systems of the extrasplanchnic circulation is essential for maintaining the systemic MAP.

Vasopressin analogues have attracted the most attention, given their preferential vasoconstrictor action on the splanchnic versus the renal vascular bed. Terlipressin (triglycyllysine vasopressin) is a synthetic analogue of vasopressin that apart from having a greater effect on the vascular vasopressin receptors (V_1) than the renal vasopressin receptors (V_2) is a prodrug requiring transformation to the active form, lysine vasopressin. Because of this, terlipressin has a prolonged half-life and can be given as an intravenous bolus instead of a continuous intravenous infusion. This significantly reduces the incidence of systemic ischemic complications. Long-term prospective studies^{13–17} and a large retrospective study¹⁸ in patients with type 1 and type 2 HRS have shown that terlipressin combined with daily albumin infusion improved renal function in 60% of the treated patients, with 37% surviving beyond 1 month, 60% without OLT. Reversal of HRS was associated with improved survival.^{16,18} The efficacy of terlipressin in the treatment of HRS has recently been confirmed in four randomized trials (Fig. 72.8).^{19–22} Terlipressin was given at a starting dose of 2 to 6 mg/day, and in two studies, the dose was titrated upward on the basis of response to a maximum dose of 12 mg daily. Both treated patients and controls were given

daily albumin infusion of 20 to 40 g/day. Reversal of HRS was associated with improved survival, but a significant improvement in survival compared with controls was observed in only one study.²¹ The inclusion of patients with more severe renal failure in the treated group²⁰ and the unexpected high response and survival rate in controls²² may explain the inability of some of these studies to show a survival benefit of treatment despite success in reversing HRS. The latter is likely to be due to the more aggressive use of albumin infusion in these studies as such an approach has been shown to reverse HRS in a high proportion of patients.²³

Recurrence rates of HRS after successful treatment are variable and tend to be more common in type 2 than in type 1 HRS.^{13,14,16,17,20,22} Re-treatment with terlipressin is successful in most patients.^{14,16,20} Younger age,^{18,21} lower baseline serum creatinine level,²² Child-Pugh score of 12 or lower,^{18,21} and administration of albumin¹⁶ are independent predictors for a successful response to treatment; Child-Pugh score (≤ 12)^{16,18,20,21} and model for end-stage liver disease (MELD) score²² were independent predictors for patient survival. Transient abdominal pain and diarrhea after the first dose of terlipressin treatment are common. Significant ischemic side effects attributed to terlipressin occurred in an average of 4% of cases.^{13-17,19-22} Deterioration of liver function or hepatic encephalopathy during treatment was not observed in most studies.^{13,14,18,20,22}

Intravenous vasopressin has been used as an alternative to terlipressin in the treatment of HRS in countries where this drug is not available and was successful in reversing type 1 and type 2 HRS in 42% of patients in a retrospective study.²⁴ Responders had significantly lower mortality and higher liver transplantation rate than nonresponders did. No adverse effect related to therapy was observed.

Intravenous norepinephrine combined with intravenous albumin and furosemide reversed type 1 HRS in 10 of 12 patients; three survived with OLT, and four survived for a median of 332 days without OLT.²⁵ With use of a similar dosing regimen, two

randomized comparative studies showed that norepinephrine is as effective as terlipressin in the treatment of type 1 and type 2 HRS (see Fig. 72.8).^{26,27} All recurrences were successfully re-treated with the original regimen. Significant treatment-related side effects were low, and the cost of treatment with norepinephrine was 3 and 15 times lower, respectively, than with terlipressin.

Administration of midodrine (an orally active α -mimetic drug), subcutaneous octreotide, and albumin infusion was successful in reverting type 1 HRS in all of five treated patients, compared with only one of eight patients treated with subpressor dose of dopamine and albumin.²⁸ Four of five treated patients survived longer than 1 month, two with OLT and two without OLT. Treatment could be maintained for up to 2 months, with three patients receiving treatment at home. Side effects were self-limited, including tingling, goose bumps, and diarrhea. These findings were confirmed in a retrospective study that used a similar drug dosing regimen but without daily albumin infusion.²⁹ Significant side effects of treatment were observed in only one treated patient. In another study, oral midodrine given in a lower dose in combination with intravenous octreotide (25-µg bolus followed by 25 µg/h) and albumin for 14 ± 3 days (range, 5 to 47 days) reversed type 1 HRS in 10 of 14 patients.³⁰ Octreotide may contribute to normalizing the response of the vasodilated splanchnic arterial vessels to midodrine, thereby avoiding the extrasplanchnic side effects of vasoconstrictor therapy. Thus, midodrine in combination with octreotide is an effective alternative treatment of type 1 HRS and allows treatment on an outpatient basis. In contrast, monotherapy with octreotide was ineffective in a randomized prospective double-blind placebo crossover trial³¹ and in a retrospective study in HRS.²⁴

Transjugular Intrahepatic Portosystemic Stent-Shunt

Portal hypertension is central in the pathogenesis of the homeostatic abnormalities in HRS. The high operative mortality

precludes side-to-side portacaval shunts in HRS patients. Transjugular intrahepatic portosystemic stent-shunting (TIPS) creates a parenchymal track between branches of the hepatic and portal vein (Fig. 72.9). In experienced hands, operative mortality rates are 1% to 2%, and the morbidity rate is 10%. Procedure-related complications include intra-abdominal bleeding, cardiac arrhythmia, shunt migration and thrombosis, hemolytic anemia, fever, infection, and reactions to radiocontrast media (including nephrotoxicity). The resultant diversion of portal blood flow

from the liver to the systemic circulation may result in transient deterioration of liver function and development of encephalopathy. In an earlier study, TIPS improved renal function in six of seven HRS patients (all with Child-Pugh score <12) and achieved a mean survival of 4.7 (0.3 to 17) months.³² A long-term study of 31 nontransplantable cirrhotic patients with HRS (14 type 1 and 17 type 2) without severe liver failure confirmed that TIPS improved renal function and survival compared with controls.³³ Shunt stenosis and occlusion occurred in seven patients and could be treated in six by balloon dilation or stent prolongation, and 11 developed hepatic encephalopathy during follow-up.

Combined TIPS and intravenous terlipressin therapy was performed in nine patients with type 2 HRS.¹⁷ All seven patients who responded to terlipressin and relapsed after treatment cessation responded to TIPS. In another study, TIPS was performed in five patients with type 1 HRS after successful treatment with midodrine, octreotide, and albumin.³⁰ Complete normalization of renal function was observed in all patients 12 months after TIPS. In both studies, improvement or elimination of ascites was an added benefit.

Extracorporeal Liver Support Therapy

Extracorporeal liver support therapy, as a bridge to OLT, relies on biologic (hepatocytes or whole liver organ from human or animal source in an *ex vivo* perfusion system) or nonbiologic methods, including hemodialysis, hemofiltration, plasma exchange, and hemoperfusion through charcoal or other adsorbent. In a small prospective randomized controlled trial, a mean of five treatments with the molecular adsorbents recirculating system (MARS) effectively removed albumin-bound toxic metabolites (i.e., bilirubin and bile acids), improved renal function, and prolonged survival in eight patients (mean survival, 25 ± 5 days) with type 1 HRS and severe liver failure compared with five control patients treated only with hemodiafiltration (mean survival, 5 ± 2 days).³⁴ In another study of eight encephalopathic patients (five with type 1 and two with type 2 HRS), MARS improved renal function, bilirubin, prothrombin time, grade of encephalopathy, MAP, systemic vascular resistance, and cardiac output, with four patients still alive without OLT at 3 months.³⁵ In both studies, therapy was well tolerated. Thrombocytopenia was the only MARS-related adverse event observed.

Renal Replacement Therapy

Hemodialysis and peritoneal dialysis in HRS patients with advancing uremia are both difficult. Conventional hemodialysis is hampered by the invariable systemic hypotension, and the efficacy of peritoneal dialysis is reduced by the presence of large amounts of ascites creating huge “dead spaces.” The latter could be overcome by complete drainage of the abdominal fluid between cycle exchanges, but this would result in substantial derangement of body fluid distribution, with resultant hypotension. Continuous venovenous hemofiltration (CVVH) has been advocated for the treatment of advancing uremia in HRS.³⁶ CVVH allows the administration of nutritional support, which is often vital to the survival of these patients and would optimize their condition before OLT. Furthermore, CVVH is associated with a fall in intracranial pressure in patients with HRS, an important consideration, especially in patients suffering from hepatic encephalopathy, whereas an increase is observed with intermittent hemofiltration or hemodialysis. It is therefore also safer to use in patients who suffer from severe hepatic encephalopathy.

Figure 72.9 Transjugular intrahepatic portosystemic stent-shunt. **A**, An intrahepatic track has been created between the right hepatic vein and the right portal vein. **B**, The track is dilated (arrow) and stented, creating a shunt as demonstrated on shuntogram. (Courtesy Dr. W. K. Tso, Queen Mary Hospital, Hong Kong.)

lopathy. Anticoagulation should be minimized or may be avoided totally, especially in patients with preexisting coagulopathy, by giving the replacement fluid in the predilutional mode. When anticoagulation is needed, conventional or low-molecular-weight heparin is generally recommended. Because the liver plays a significant role in citrate metabolism, dose adaptation and close metabolic monitoring would be required for regional citrate anticoagulation, especially after prolonged use. Bicarbonate should be used instead of lactate as the buffer for the replacement solution to minimize metabolic acidosis. MARS may be combined with either CVVH or hemodialysis for the treatment of HRS. This approach may be most desirable in patients who also suffer from severe hepatic encephalopathy. For both MARS and CVVH, the site of dialysis catheter placement should be carefully chosen in a potential liver transplant recipient so that the right jugular and right femoral vein may be preserved for cannulation when going into bypass at the time of liver transplantation.

Orthotopic Liver Transplantation

OLT is the only definitive treatment of patients suffering from HRS. After OLT, the 5-year patient and graft survival rates are about 10% lower for those who had HRS before OLT compared with those who did not.³⁷ Although renal function improves after transplantation in HRS patients, it never reaches that observed in non-HRS patients.³⁷ Pretransplantation or post-transplantation dialysis did not affect the clinical outcome. The incidence of end-stage renal disease in the HRS group was 7%, compared with 2% in the non-HRS group. Retransplantation rates and

long-term liver function were similar in the two groups.³⁷ Thus, OLT is associated with comparable liver outcome but inferior renal outcome in patients with HRS compared with those without HRS. This problem cannot be overcome by performing combined kidney and liver transplantation in HRS, which overall produces outcomes no better than with OLT alone.³⁸ However, in the subgroup of patients with HRS who required prolonged pretransplant dialysis for more than 2 months, combined kidney and liver transplantation did confer an advantage in patient survival and use of hospital resources.³⁹ In addition, the liver appeared to be immunoprotective for the kidney. The reason for the inferior outcome of HRS patients after OLT is most likely related to the enhanced nephrotoxic effect of calcineurin inhibitors in ischemic kidneys. As the hemodynamic and neurohumoral abnormalities associated with HRS take time to resolve, these drugs should be withheld in the first few days after OLT to give the kidney a chance to recover. A study showed that pretransplantation reversal of HRS allows HRS patients to achieve renal and liver outcomes comparable to those of patients without HRS after OLT.⁴⁰ These results suggest that HRS should be treated before OLT, and this strategy may improve the renal outcome in these patients.

THERAPEUTIC STRATEGY AND CHOICE OF TREATMENT MODALITIES

Figure 72.10 is an algorithm for the management of HRS. Recent recommendations for therapy have also been

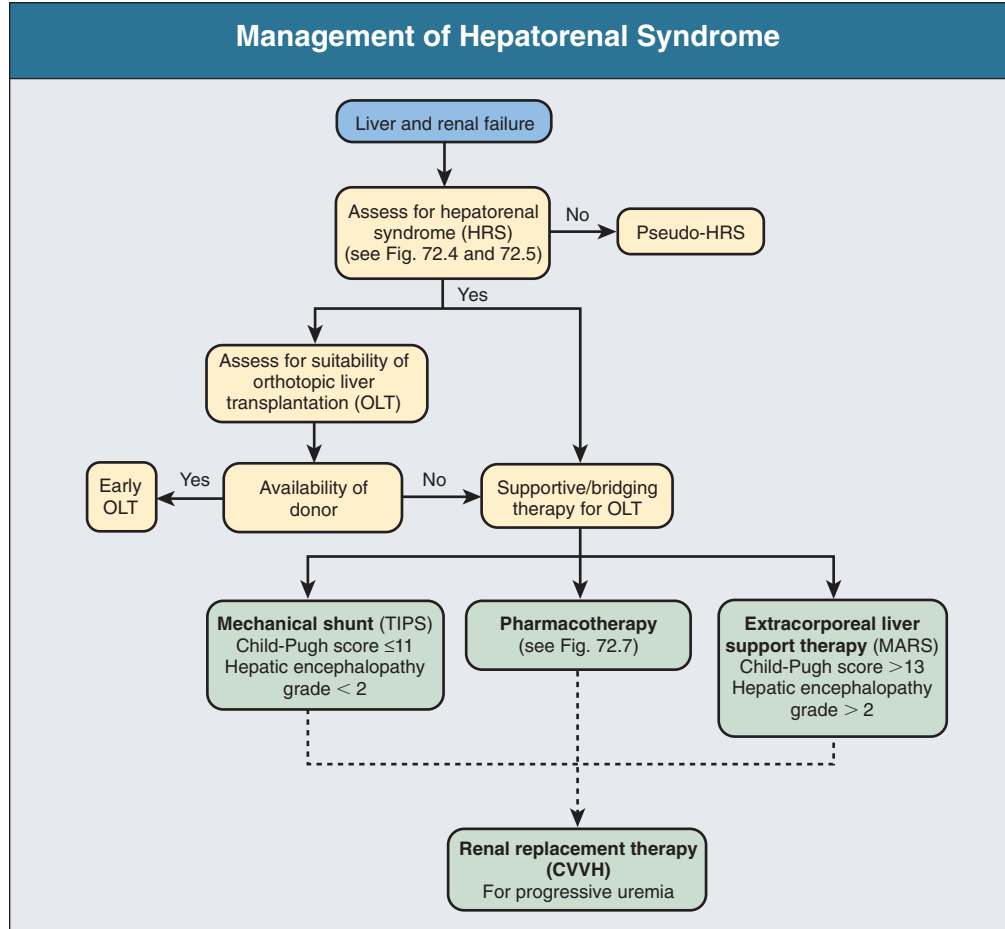

Figure 72.10 Algorithm for the management of hepatorenal syndrome. CVVH, continuous venovenous hemofiltration; MARS, molecular adsorbents recirculating system; TIPS, transjugular intrahepatic portosystemic stent-shunt.

published by the Consensus Workshop of the International Ascites Club.⁷

OLT is undoubtedly the treatment of choice for patients suffering from HRS, but other treatments described earlier may be used as a bridge to OLT, and they may improve the renal outcome after successful OLT. In patients who are not transplantation candidates, these treatments are their only chance for increased survival and, in some cases, may improve their condition to an extent that may allow them to be reconsidered for transplantation. The choice of therapeutic modalities depends on the availability of resources and expertise on the one hand and the severity of underlying renal and liver failure and the general condition of the patient on the other. All patients without clinical evidence of significant atherosclerotic or cardiovascular disease should be considered for vasoconstrictor therapy combined with albumin infusion. In patients with relatively well preserved liver function (bilirubin <5 mg/dl and Child-Pugh score ≤11) without severe hepatic encephalopathy (grade <2) or history of recurrent encephalopathy, concurrent severe bacterial infection, and serious cardiovascular or pulmonary disease, TIPS should be considered, especially in patients with recurrence after vasoconstrictor therapy, a situation more commonly observed in HRS type 2 patients. In these patients, TIPS may have the added benefit of relieving refractory ascites. TIPS also appears to achieve complete normalization of renal function in selected patients after an initial successful response to vasoconstrictor therapy. In patients with severe liver failure (Child-Pugh score >13) and severe hepatic encephalopathy (grade >2), MARS should be considered. In patients with advancing renal failure, CVVH is the treatment of choice and may be combined with other therapeutic modalities, especially MARS. Among the vasoconstrictor therapies, intravenous terlipressin, combined with daily albumin infusion, is most established and is the preferred therapy. In countries where terlipressin is not available, intravenous vasopressin may be used as an alternative. If cost is an important consideration, intravenous norepinephrine is a good choice. Oral midodrine combined with subcutaneous octreotide is another alternative and has the advantage in that it can be administered on an outpatient basis.

Principles of Drug Therapy, Dosing, and Prescribing in Chronic Kidney Disease and Renal Replacement Therapy

Matthew J. Cervelli, Graeme R. Russ

Renal impairment can alter drug pharmacokinetics and pharmacodynamics, and consequently patients with renal impairment are at risk for adverse effects. In addition, these patients take multiple drugs and are at high risk for drug interactions and drug-related problems.¹ To prescribe safely and effectively in these patients, clinicians should be familiar with the pharmacokinetic behavior of drugs in varying stages of renal impairment and renal replacement therapy (RRT) and ideally rely on data from these populations. Unfortunately, such information is not always readily available. Exclusion of these patients from clinical studies can lead to restrictive licensed recommendations. Although newer drugs are usually studied in small numbers of renally impaired patients, the applicability of this information to individual patients is difficult. This chapter describes pharmacokinetic principles and highlights common prescribing issues in renal impairment, dialysis, and transplantation. Specific dose recommendations and pharmacokinetic data are not included but can be obtained from references developed specifically to provide concise, reliable, and practical information to assist decision-making for prescribing in renal impairment, dialysis, and transplantation.²⁻⁵

PHARMACOKINETIC PRINCIPLES

Pharmacokinetics describes the behavior of a drug (or metabolite) with regard to absorption, distribution, metabolism, and elimination (Figs. 73.1 and 73.2).^{6,7}

Absorption

Bioavailability

Absolute bioavailability (F) is the portion of a drug dose that appears in the systemic circulation after administration by an alternative route compared with the intravenous route. Drugs given intravenously have 100% bioavailability, reach the central compartment directly, and usually have a rapid onset of action. Drugs given by alternative routes pass through a series of biologic membranes before entering the systemic circulation so that only a fraction may reach the circulation.

After oral administration, the liver can metabolize a drug during “first pass” when it is absorbed or later when it is delivered through systemic blood flow. First-pass metabolism can significantly reduce absorption. The gastrointestinal mucosa also acts as a barrier to absorption by metabolizing drugs or retarding absorption.⁸ Renal impairment can influence absorption, although the effect is difficult to quantify and the number of drugs for which this is clinically significant is limited.

Gastrointestinal edema can limit oral absorption of furosemide. Nausea and vomiting from uremia can impair absorption and contact time between the drug and gastrointestinal mucosa. In advanced uremia, the alkalinizing effect of salivary urea may decrease absorption of drugs optimally absorbed in an acid milieu. Oral iron requires acidic conversion from the ferrous to ferric state for absorption, and acid suppression can impair absorption. Commonly prescribed metallic phosphate binders can decrease drug absorption by forming nonabsorbable complexes with drugs (Fig. 73.3).⁹ Changes in cardiac output in renal failure can reduce the rate and extent of absorption for drugs with significant first-pass metabolism. Increased absorption in renal impairment from reduced first-pass metabolism is seen with some β -blockers, dextropropoxyphene, and dihydrocodeine. Comorbidities in renal patients also have an effect; for example, absorption can be erratic in patients with diabetic nephropathy as coexisting gastrointestinal neuropathy slows gastric emptying and the rate of drug absorption.

Distribution

Volume of Distribution

After absorption, drugs may distribute from plasma to an extravascular compartment. Each drug has a characteristic volume of distribution (V_D), which is really an apparent V_D because it does not correspond to an anatomic space but instead relates the amount of drug in the body to its plasma concentration. For drugs with low plasma concentration relative to dose, V_D may exceed total body water. Drugs that are restricted to the circulation have a low V_D . V_D is used to calculate the loading dose to achieve a desired plasma concentration ($V_D = \text{dose}/[\text{plasma}]$). Water-soluble drugs tend to be restricted to the extracellular fluid space and have a relatively small V_D . Lipid-soluble drugs penetrate body tissues and have a large V_D . Increased V_D can occur in edema, ascites, or infection, particularly for water-soluble drugs. If usual doses are given, low concentrations result. Conversely, muscle wasting or volume depletion can decrease the V_D of water-soluble drugs, and usual doses produce high concentrations.

Plasma Protein Binding

Drugs can bind extensively to plasma proteins.¹⁰ The free (or unbound) fraction of a drug is usually the portion that exerts a pharmacologic effect. If protein binding is reduced, a greater free fraction is available for any given total drug concentration, which may increase drug activity. Organic acids usually have a single binding site on albumin, whereas organic bases have multiple

binding sites on glycoproteins. Protein binding can be altered in renal impairment, especially when serum albumin is low (e.g., nephrotic syndrome) or when uremic toxins displace drugs from binding sites (Fig. 73.4). Predicting the effect of changes in protein binding is difficult because even though more free drug is available at the site of action, more is available for metabolism or renal excretion. Hence, lower plasma concentrations can occur and drug half-life may decrease rather than increase. Phenytoin, for example, has marked decreases in protein binding in renal impairment, and toxicity can occur despite normal or low total plasma concentrations because of an increase in the active

free fraction. With albuminuria, bound drug may also be lost, which may partially explain the refractoriness of nephrotic patients to diuretics. In chronic kidney disease (CKD), high plasma levels of α_1 -acid glycoprotein are induced in acute and chronic inflammation, which can increase drug binding.

Metabolism

Drug metabolism is primarily a hepatic function converting drugs to more water-soluble entities to promote elimination by the kidneys and bile. Despite the assumption that nonrenal

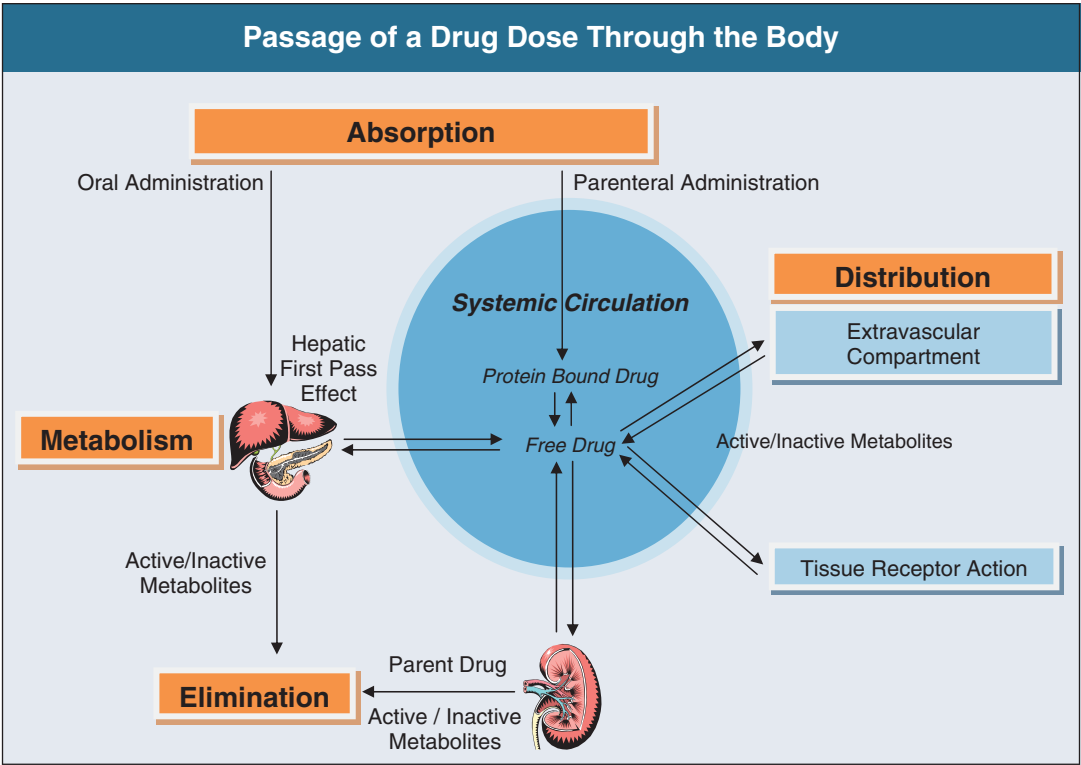

Figure 73.1 Passage of a drug dose through the body.

Figure 73.2 Pharmacokinetic parameters.

Pharmacokinetic Parameters		
Parameter	Definition	Application
Bioavailability (<i>F</i>)	% of a dose that appears in the systemic circulation after administration by an alternative route compared with intravenously	Determines the amount of drug reaching the systemic circulation
Volume of distribution (<i>V_D</i>)	Proportionality constant relating the amount of drug in the body at a given time to a simultaneously occurring drug concentration in plasma, blood, or other reference fluid at an identical time	Determines the size of loading doses
Clearance (<i>Cl</i>)	Proportionality constant between rate of drug elimination from the body (units = mass/unit time) and the concentration of the drug in plasma or blood at the same point in time	Determines the maintenance dose
Half-life (<i>t_{1/2}</i>)	Time taken for the drug concentration in plasma to fall to half its current value	Determines frequency of administration and time to steady state

Effect of Food and Phosphate Binders on Oral Drug Absorption

Drug	Effect of Food
Captopril	Decrease in serum drug levels
Bisphosphonates (oral)	Significantly reduces drug absorption
Cinacalcet	Significantly increases drug absorption
Iron (oral)	Decreases absorption
Ketoconazole/Itraconazole	Increases absorption with reduced pH
Sirolimus	High fat meals increase absorption
Tacrolimus	Reduces drug absorption
Drug	Effect of Metallic Phosphate Binders
Bisphosphonates (oral)	Ca ²⁺ based binders significantly reduce absorption
Fluoroquinolones	Reduction in absorption
Tetracycline	Reduction in absorption
Thyroid hormones	Reduction in absorption

Figure 73.3 Effect of food and phosphate binders on oral drug absorption.

Protein Binding of Drugs in Renal Disease

Albumin: Binding Sites for Acidic Compounds	
Major Effects	Minor Effects
Barbiturates (↓)	Ascorbic acid
Benzodiazepine	Valproate (↓)
Carbamazepine	Fatty acids
Fibrates	Nafcillin
Furosemide (↓)	Phenylbutazone (↓)
Mycophenolate mofetil	Probenecid
Penicillins	Thiopental (↓)
Phenytoin (↓)	Warfarin (↓)
Sulfonamides (↓)	Thyroxine (↓)
Globulins: Binding Site for Basic Compounds	
Major Effects	Minor Effects
Digoxin (↓)	Adenosine
Methadone	Amitriptyline
Propranolol	Chloramphenicol

Figure 73.4 Protein binding of drugs in renal disease. (↓) indicates reduced protein binding in renal impairment. For all other drugs listed there is increased protein binding. The therapeutic effect is however not easily predicted (see text).

clearance is unchanged in renal impairment, renal impairment can alter and slow drug metabolism.¹¹ For high hepatic extraction drugs, this may increase bioavailability. Importantly, some drugs have renally cleared active or toxic metabolites that, although insignificant in normal renal function, can accumulate in renal impairment.

Mathematics of Drug Elimination

Total Body Clearance = drug dose / AUC

Renal Clearance = Total amount of drug in urine / Plasma drug concentration

Total amount of drug in urine = [drug] × volume of the sample collected in a fixed time

Drug half-life ($t_{1/2}$) = $V_D \times 0.693 / \text{Clearance}$

Figure 73.5 Mathematics of drug elimination. AUC = area under the concentration-time curve; V_D = volume of distribution (dose/blood concentration).

Elimination

The kidney is the most important organ for drug and metabolite elimination. Terms to describe drug clearance are shown in Figure 73.5. Total drug clearance equals the apparent volume of blood or plasma from which the drug is cleared per unit of time and is expressed as the dose divided by the area under the drug concentration curve (AUC). Half-life describes the time taken for plasma concentrations to halve and is related to V_D and clearance. Quantitation of drug elimination by the kidney is expressed as renal clearance, which depends on renal blood flow and the ability of the kidney to remove the drug. Renal drug clearance is the balance of its glomerular filtration rate (GFR), renal tubular secretion, and tubular reabsorption. Glomerular filtration depends on molecular size (<10 kD), charge, and protein binding (increased when binding decreases). Secretion of drugs eliminated by tubular transport may change in renal disease, but measurement of tubular function is difficult. Practically, as GFR decreases, drugs dependent on tubular secretion are also excreted more slowly. Assuming no change in nonrenal clearance, as GFR falls, clearance of drugs (and metabolites) eliminated by the kidney decreases, and their half-life is prolonged.

PRESCRIBING PRINCIPLES IN CHRONIC KIDNEY DISEASE AND RENAL REPLACEMENT THERAPY

Ideally, the pharmacokinetics of a drug at varying stages of renal impairment should be compared with that at normal function. This approach underpins many dose modification recommendations. However, lack of reliable data and individual patient factors limit such generalities, and clinical judgment about a particular patient's ability to handle a drug is vital.¹² Dose nomograms, tables, and computer recommendations are helpful but not necessarily associated with better outcomes. Any fixed approach to dosing will probably fail because of the clinical complexity of renal failure. Physicians should use clinical judgment to evaluate every situation individually, choose a dose regimen based on factors in that patient, and continually re-evaluate the response to therapy.

Initial Assessment and Laboratory Data

A targeted history is important in assessing dose in renal impairment. Previous drug efficacy or toxicity should be determined. The current drug list should be reviewed for potential interactions or nephrotoxins. Physical and laboratory parameters

indicate volume status, height, weight, and the presence of extra-renal disease (e.g., liver).

Estimating Renal Function for Drug Dosing

Estimating renal function is essential in assessing drug dose in renal impairment. The greater the degree of renal impairment, the greater the potential need for dose modification. With exceptions, dose modification is usually not clinically necessary until GFR is below 30 mL/min. Assessment of renal function for drug dosing is not a precise science, and what is essential for clinical decision-making is awareness that a patient's renal function is impaired, and approximately to what extent, rather than knowing the precise GFR.¹³ For drug prescribing, renal impairment is usually graded as mild (30 to 60 mL/min), moderate (10 to 30 mL/min), or severe (dialysis). For drug dosing, methods of estimating GFR are sufficient (see Chapter 3). The Cockcroft-Gault equation has been the most widely used and accepted method for assessing renal drug dosing. The Modification of Diet in Renal Disease (MDRD) formula is not routinely recommended and, if not corrected for body surface area, can lead to recommendations different from those obtained by the Cockcroft-Gault equation. An important limitation of many renal function estimates is the inaccuracy of single-point estimates when renal function is rapidly changing. This may lead to overestimation or underestimation of renal function and underdosing or overdosing of drugs. In severe acute kidney injury (AKI), the decline in GFR is so rapid that patients should be dosed as if the GFR is below 10 mL/min. The opposite is true in patients with rapidly improving renal function after AKI or in the early post-transplantation phase.

Activity and Toxicity of Metabolites

It is essential to consider the activity (and toxicity) of drug metabolites in addition to that of the parent drug itself. Renally cleared metabolites can accumulate, leading to enhanced drug action or toxicity (Fig. 73.6).

Fraction of Active Drug (and Active or Toxic Metabolite) Excreted Unchanged in Urine

The greater the fraction of active drug or metabolite excreted unchanged by the kidneys (f_e), the greater the need for dose

modification. However, it is usually clinically necessary to modify doses only if the f_e of the active component is more than 25% to 50%. The reported f_e is often determined from studies that do not distinguish between parent drug and metabolites. The contribution of inactive nontoxic metabolites to overall renal drug elimination may exaggerate the potential for harm. Active or toxic metabolites should be assessed separately for their dependence on renal excretion in the same way as the parent drug (Fig. 73.7).

Therapeutic Index of the Drug or Metabolites

The decision to dose modify in renal impairment is influenced by the therapeutic index or therapeutic window of the drug. The therapeutic window is the range of plasma drug concentrations

Drugs with Active/Toxic Metabolites Requiring Dose Modification		
Drug	Active Metabolite	Consequence
Allopurinol	Oxypurinol	
Cefotaxime	Desacetylcefotaxime	
Glyburide	4- <i>trans</i> -Hydroxyglibenclamide 3- <i>cis</i> -Hydroxyglibenclamide	Hypoglycemia
Morphine	Morphine-6-glucuronide	CNS side effects
Tramadol	O-Desmethyltramadol	CNS side effects
Venlafaxine	O-Desmethylvenlafaxine	CNS/ cardiovascular side effects
Drug	Toxic Metabolite	Consequence
Dapsone	Monoacetylated metabolite	
Mepiridine (pethidine)	Normeperidine (norpethidine)	CNS (seizures)
Nitroprusside	Thiocyanate	Cyanide toxicity
Procainamide	N-Acetylprocainamide (NAPA)	Arrhythmia
Propoxyphene	Norpropoxyphene	Cardiac toxicity

Figure 73.6 Drugs with renally cleared active or toxic metabolites. CNS, central nervous system.

Figure 73.7 Fraction of drug/metabolite excreted in urine. In this hypothetical example, 10% of the dose is excreted unchanged in urine ($f_e = 10\%$); 50% of the dose is metabolized to inactive metabolite M1, which is then 100% excreted renally; 30% of the dose is metabolized to inactive metabolite M2, which is 100% renally excreted; and the remaining 10% is excreted unchanged in bile. For this drug, the total excretion of drug dose in urine is 90%. However, this 90% comprises 10% as parent drug and 80% as inactive metabolites, and dose modification is probably not essential even in severe renal impairment. Total renal excretion of the dose is 90%; however, the clinically significant fraction of active drug excreted in urine is 10%.

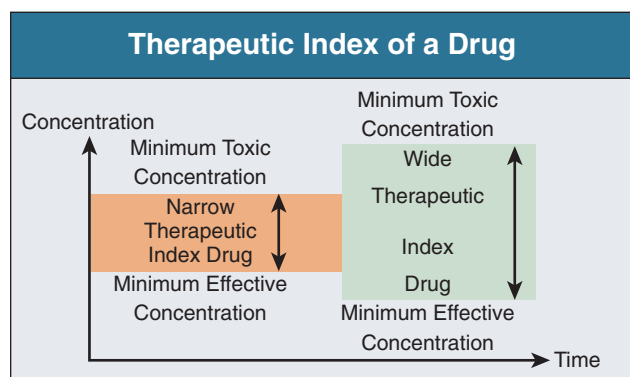

Figure 73.8 Therapeutic index of a drug.

spanning the minimum concentration for clinical efficacy and toxicity. The therapeutic index is the ratio of these concentrations (Fig. 73.8). If the therapeutic window is wide (e.g., many penicillins), there may be no clinical need for dose modification despite significant renal elimination. If the therapeutic window is narrow (e.g., digoxin), dose modification is more critical. The clinician should judge the clinical relevance of increased exposure to drug or metabolites.

Avoid Nephrotoxic Drugs

A wide range of drugs can cause nephrotoxicity (Fig. 73.9; see also Fig. 66.7). Idiosyncratic nephrotoxicity (e.g., interstitial nephritis) is unpredictable and independent of dose. Predictable hemodynamic-related nephrotoxicity can occur with angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), nonsteroidal anti-inflammatory drugs (NSAIDs), diuretics, antihypertensives, and laxatives. Direct tubular nephrotoxins include aminoglycosides, vancomycin, amphotericin, cisplatin, calcineurin inhibitors, and radiographic contrast media. Obstructive uropathy can occur with tubular crystallization of acyclovir, statin-induced rhabdomyolysis, or tricyclic antidepressants. In dialysis patients who do not have potential for further significant loss of renal function, use of nephrotoxic drugs may be acceptable.

Drugs That Aggravate the Metabolic Effects of Renal Impairment

A number of drugs have no direct adverse effect on renal function but when used in renal impairment can aggravate the metabolic consequences of renal failure. Hyperkalemia is worsened with potassium supplements, potassium-sparing diuretics, eplerenone, ACE inhibitors, ARBs, and the catabolic effects of tetracycline (also exacerbates uremia). Many renal patients are intolerant of sodium loading, which may provoke fluid overload and hypertension. Sodium-containing drugs and those that promote sodium and water retention should be used cautiously.

Effect of Renal Impairment on Pharmacodynamic or Physiologic Mechanisms

Renal disease may alter a pharmacodynamic response or physiologic process that in turn affects clinical response. For example, the inability of impaired kidneys to activate vitamin D precursors means that vitamin D₂ and D₃ therapy may be less effective in

renal impairment. Patients with renal impairment often have a coagulopathy due to the effects of uremia on platelet function and may be more prone to the bleeding complications of anti-coagulant and antiplatelet therapy.

Effect of Renal Impairment on the Concentration of Drug at the Site of Action

Renal impairment can significantly alter drug concentration at the site of action. Some diuretics and antibiotics are clinically ineffective in renal impairment because they do not achieve adequate concentrations at their site of action in the renal tubules or bladder. This may preclude the use of particular drugs (e.g., thiazide diuretics, nitrofurantoin, and hexamine hippurate) or require increased doses of others (e.g., loop diuretics).

Location of Drug Action

Drugs that have negligible bioavailability and that are used for a local or topical effect may be used safely at normal dose despite toxicity with systemically administered doses. These include topical NSAIDs, nebulized gentamicin, and oral vancomycin.

Method of Administration

In fluid-restricted renal patients, administration of intravenous drug infusions with approved fluid volumes may be undesirable. When administration will exceed daily fluid restrictions, consider alternatives or more concentrated solutions if physiochemical parameters allow. Similarly, oral drug administration with large fluid volumes (e.g., bisphosphonates) may not be advisable. In severe nausea and vomiting, essential immunosuppressants should be administered intravenously.

Drug Interactions

Pharmacokinetic drug interactions are frequently problematic, and awareness of clinically significant interactions is essential, especially for those receiving transplant immunosuppressants. The most important of these are cyclosporine, tacrolimus, everolimus, and sirolimus, which are substrates of both the CYP3A4 enzyme system and P-glycoprotein that are expressed in gastrointestinal mucosa and liver.¹⁴ Co-prescription of drugs that inhibit these systems (e.g., some azole antifungals, calcium channel blockers, macrolides, and grapefruit juice) can increase absorption and reduce metabolism of the immunosuppressant, causing toxicity. Conversely, drugs that induce these systems (e.g., barbiturates, phenytoin, carbamazepine, rifampin, and St. John's wort [*Hypericum*]) can reduce absorption and increase metabolism and therefore increase the risk of rejection (Figs. 73.10 and 73.11). All drug changes in patients receiving transplant immunosuppressants should be considered for their potential to interact and appropriate dose modifications or alternatives used.

Clinical Condition of the Patient

The patient's welfare should override theoretical concerns. Higher than recommended doses may be appropriate when there is a strong clinical indication. For example, excessive reduction in initial antibiotic doses based on renal function may be inappropriate in the setting of life-threatening infection when the consequences of failed therapy are greater than potential toxicity.

Nephrotoxic Drugs		
Examples	Mechanism	Prevention/Management
ACE inhibitors/ARBs	Impairment of angiotensin II–mediated afferent arteriole dilation during renal hypoperfusion	Withdraw in renal hypoperfusion
Aminoglycosides Amikacin Gentamicin Tobramycin	In proximal tubules, aminoglycosides bind to anionic phospholipid, are delivered to megalin, are taken up into the cell, accumulate, and cause direct toxicity	Alternative if possible Monitor drug concentrations Avoid multiple daily dosing Withdraw if creatinine rises
Antifungals Amphotericin	Afferent vasoconstriction and direct action to reduce GFR Distal tubular injury via creation of pores that increase membrane permeability leading to hypokalemia, hypomagnesemia, metabolic acidosis due to tubular acidosis, polyuria due to nephrogenic diabetes insipidus	Avoid use Administer slowly with hydration Use liposomal preparation
Antivirals Acyclovir	Deposition of drug crystals → intratubular obstruction and foci of interstitial inflammation	Avoid bolus dose Reduce dose in renal impairment Hydrate during therapy
Cidofovir Foscarnet	Induces apoptosis in proximal tubule → tubular dysfunction, diabetes insipidus, renal failure Direct tubular toxicity → acute tubular necrosis, nephrogenic diabetes insipidus Crystals in glomerular capillary lumen and proximal tubular lumen	Oral probenecid and hydration Hydration
Indinavir	Crystal neuropathy, nephrolithiasis → obstructive AKI	Hydration
Calcineurin Inhibitors Cyclosporine Tacrolimus	↓ PG and ↑ 20-HETE acid production → vasoconstriction, generation of H ₂ O ₂ resulting in depleted glutathione → decreased GFR, ischemic collapse or scarring of the glomeruli, vacuolization of the tubules, and focal areas of tubular atrophy and interstitial fibrosis	Measure plasma concentrations Avoid interacting drugs Withdraw drug (switch to mTOR inhibitor)
Chemotherapeutics Cisplatin	Cis chloride replaced by H ₂ O → highly reactive OH radical → DNA injury, tubular cell death Nephrogenic diabetes insipidus, hypomagnesemia (may be persistent)	Forced diuresis and hydration
Ifosfamide	Direct tubular injury and mitochondrial damage → renal tubular acidosis, Fanconi-like syndrome, nephrogenic diabetes insipidus hypokalemia	
Intravenous immunoglobulin (sucrose-containing products)	Accumulation of sucrose in proximal convoluted tubules forms vesicle, ↑ osmolarity → cell swelling, vacuolization, and tubular luminal occlusion	Infusion rate < 3 mg sucrose/kg/min Avoid radiocontrast Avoid sucrose-containing product Hydration
Lithium	Impairment of collecting duct concentrating ability → diabetes insipidus Chronic tubulointerstitial nephropathy (tubular atrophy and interstitial fibrosis)	Measure plasma concentrations Prevent dehydration Avoid thiazides
NSAIDs	Hemodynamically induced AKI due to vasoconstriction via reduced prostaglandin production Recruitment and activation of lymphocytes → acute and chronic tubulointerstitial nephritis, with or without nephrotic syndrome	Avoid use Withdraw during hypoperfusion Withdraw (add corticosteroids)
Proton pump inhibitors	Interstitial nephritis	Withdraw (add corticosteroids)
Radiocontrast media	High osmolarity, medullary vasoconstriction, ↑ active transport in thick ascending loop of Henle → ↑ O ₂ demand	Hydration pre- and post-procedure Acetylcysteine
Sulphonamides	Intrarenal precipitation → Kidney stone formation	Fluid intake > 3 l/day and monitor urine for crystals. Alkalinize urine to > 7.15 if crystal seen

Figure 73.9 Some examples of nephrotoxic drugs. ACE, angiotensin-converting enzyme; ARBs, angiotensin receptor blockers; AKI, acute kidney injury; GFR, glomerular filtration rate; NSAIDs, nonsteroidal anti-inflammatory drugs; PG, prostaglandin.

CYP3A4 and P-glycoprotein in Drug Absorption and Metabolism

Figure 73.10 CYP3A4 and P-glycoprotein in drug absorption/metabolism. Schema for absorption and metabolism of drugs which are substrates for CYP3A4 and p-glycoprotein. Overall ~15% of ingested drug reaches the systemic circulation. 1) Enterocyte: p-glycoprotein on the apical surface of enterocytes prevents drug absorption, maintaining drug in the gastrointestinal lumen; CYP3A4 in enterocytes metabolizes drug. The net effect is ~30% of ingested drug reaches the portal circulation. 2) Hepatocyte: p-glycoprotein on the cell surface prevents drug entry into hepatocytes; CYP3A4 in hepatocytes metabolizes drug. The net effect is that drug entry to the systemic circulation is further reduced.

Methods of Dose Reduction

Loading Doses

For most drugs, steady-state concentrations are achieved after five drug half-lives. Hence, for some drugs, a loading dose is given to reduce the time to steady state. Because renal impairment may prolong the half-life, simply reducing drug doses could be a therapeutic error because this would further delay achievement of steady state. The loading dose (mg/kg) is equal to the product of the desired plasma concentration (mg/ml) and V_D (ml/kg) and is independent of clearance. Provided the desired concentration and V_D are unchanged, loading doses do not require modification in renal impairment. In some instances, V_D is altered, especially with hypoproteinemia or fluid overload. Hence, some clinicians alter the loading dose of drugs with a narrow therapeutic index, such as digoxin, in renal impairment. Aminoglycoside doses may need to be increased in fluid-overloaded or septic patients who have an increased V_D .

Maintenance Dosing

When specific pharmacokinetic information is not available, and assuming no change in nonrenal clearance, maintenance doses should be reduced in proportion to the extent of renal impairment and renal drug elimination. For example, if renal function is 50% of normal and the drug is 100% renally excreted, a

maintenance dose of 50% is required. If the drug is 50% renally cleared and the patient has 20% renal function, the dose should be 60% of normal. The dose reduction factor is usually estimated from first principles or the following formula:

$$\text{dose rate}_{(\text{in renal impairment})} / \text{dose rate}_{(\text{in normal renal function})} = (1 - fe) \times (1 - \text{fraction remaining renal function})$$

(fe = fraction of active drug excreted unchanged in urine)

Once a dose reduction factor is determined, the clinician must decide on a dose reduction method. Two methods are used either alone or in combination (Fig. 73.12).

Interval Method Because drug clearance is reduced, a reduction to the total delivered dose is achieved by administration of the same dose less frequently. This method is particularly useful when the size of the dose and peak blood concentrations are important for efficacy (e.g., aminoglycosides). If this method is used, practical dose intervals should be recommended (e.g., once daily or alternate daily) rather than inconvenient or complex intervals.

Dose Method An alternative method is to administer a smaller dose at the usual interval. This method is common especially when the size of a dose and peak concentrations are less critical

Common CYP3A4/P-gp–Mediated Interactions with Transplant Immunosuppressants (Cyclosporine, Tacrolimus, Sirolimus and Everolimus)		
Drugs that Inhibit CYP3A4 & P-gp

for efficacy. If this method is used, clinicians should consider the availability of smaller dose formulations and the ability of the patient to accurately and safely divide available dosage forms.

Combination Method In some instances, especially for drugs with a narrow therapeutic index, for which tight control of concentrations is required (e.g., digoxin), a combination of the dose and interval methods is used.

Ongoing Assessment

Even with appropriate consideration and dose modification in renal impairment, clinicians should always remain vigilant and closely monitor the response to therapy to guide dose titration.

Therapeutic Drug Monitoring

Therapeutic drug monitoring can provide objective information to guide dosing strategies and is valuable in monitoring drugs such as aminoglycosides, glycopeptides, digoxin, lithium, antiepileptics, and immunosuppressants (Fig. 73.13). Assays usually measure total blood concentrations and may significantly underestimate plasma levels of the active or free form of the drug.

Clinical Response

Ultimately, clinical response should influence the need to modify doses. Doses should be carefully titrated according to the desired response and adverse effects. For example, blood pressure offers

Figure 73.12 Methods of dose reduction. **A**, Interval method. **B**, Dose method. **C**, Combination method.

the best guide for dosing of antihypertensives; blood glucose concentration and HbA_{1c} for monitoring of oral hypoglycemics; and renal function for toxicity from calcineurin inhibitors, ACE inhibitors, or ARBs.

Extracorporeal Drug Losses

Dialysis drug clearance may significantly reduce drug efficacy if it is not accounted for.^{5,7} Alternatively, it may be used in overdose to assist drug removal (see Chapter 94). Studies of drug clearance with different RRT modalities have often used variations in dialysis technique that alter drug clearance and make it difficult to compare results. In particular, many older studies before the 1990s reported data by standard hemodialysis with low-flux membranes, which are less efficient at drug removal than the high-flux membranes now widely used. Many recommendations report the effect of dialysis on the clearance of specific drugs and the need for supplemental doses. Clinically, supplemental doses are rarely used, especially if less than 30% of the drug is cleared or the drug has a wide therapeutic index. Rather, drugs known to be significantly cleared by dialysis should be dosed after dialysis (Fig. 73.14). When drugs are given in multiple daily doses, at

Therapeutic Drug Monitoring in Renal Impairment	
Drug	Therapeutic Range When to draw sample
Aminoglycosides (24-h dosing)	Peak (30 min after a 30-min infusion) Trough (6–12-h after dose)
Gentamicin	Peak: >10 mg/l
Tobramycin	Trough: depends on time post dose 0.5–2 mg/l
Amikacin	Peak: >30 mg/l Trough: depends on time post dose 1.5–6 mg/l
Immunosuppressants	
Cyclosporine	C ₀ (trough): 150–400 µg/ml C ₂ (2-h post dose): 1200–1500 µg/ml AUC ₀₋₄ : >4400 µg/ml/h
Tacrolimus	C ₀ (trough): 4–12 µg/ml
Sirolimus	C ₀ (trough): 5–15 µg/ml
Antiarrhythmics	
Digoxin	0.8–2.0 µg/ml (trough at least 6-h after dose)
Lidocaine	1–5 µg/ml 8-h after IV infusion starts or changed
Antipsychotics	
Lithium	Acute: 0.8–1.2 mmol/l (trough) Chronic: 0.6–0.8 mmol/l (trough)
Antiepileptics	
Carbamazepine	4–12 µg/ml (trough prior to dosing)
Phenytoin	10–20 µg/ml (trough prior to dosing)
Free phenytoin	1–2 µg/ml (trough prior to dosing)
Phenobarbital	15–40 µg/ml (trough prior to dosing)
Valproic acid	40–100 µg/ml (trough prior to dosing)
Vancomycin	Trough: 10–20 mg/l

Figure 73.13 Therapeutic drug monitoring in renal impairment. Target levels are dependent on assay methodology and clinical context.

least one of the daily doses should be administered soon after the completion of dialysis. For some drugs for which the relative time of administration is important (e.g., sleeping tablets, SSRIs, and bisphosphonates), this will take precedence over dialysis-related issues.

Hemodialysis

Hemodialysis drug clearance occurs mainly by passive diffusion along a concentration gradient but also by convective movement of soluble drug with ultrafiltrated plasma water.^{7,15} The efficiency of drug removal depends on physiochemical drug properties. As molecular size decreases (<500 daltons) and water solubility increases, drug removal increases. Conversely, as protein binding and V_D increase, dialysis clearance decreases. Hemodialysis factors influencing drug removal include membrane type and surface area, blood flow rates, and dialysis frequency and duration. High-flux membranes have larger pore sizes and allow removal of molecules of 500 to 1500 daltons. Hemodialysis can remove drug from plasma faster than it can redistribute from tissue, so drug concentrations determined from samples drawn soon after beginning or completion of

hemodialysis may be low. Samples should preferably be drawn before dialysis or about 1 to 2 hours after to allow drug redistribution.

Peritoneal Dialysis

Many drug properties that affect removal by hemodialysis also apply to peritoneal dialysis, but peritoneal dialysis is usually less efficient.¹⁶ For significant removal by peritoneal dialysis, the drug must have a very low V_D and low protein binding. For most drugs, there is little evidence of significant removal during chronic peritoneal dialysis. A few studies have examined drug clearance from automated peritoneal dialysis that uses large volumes of short dwells at night, often accompanied by one or more longer daytime dwells. Clearance of some drugs on automated peritoneal dialysis is increased because of the increased drug concentration gradient between blood and dialysate. Increased drug dialyzability may occur with increased peritoneal dialysate flow rates or during peritonitis.

Continuous Renal Replacement Therapy

Drug clearance by continuous RRT (CRRT) with arteriovenous or venovenous hemofiltration, hemodialysis, or hemodiafiltration differs from intermittent hemodialysis.¹⁷ Relying on continuous ultrafiltration of plasma water, CRRT can remove large quantities of ultrafilterable drug. CRRT generally uses membranes with larger pore sizes and involves convective transport of solute. Hence, these methods allow the passage of larger molecules (up to 5000 daltons). A large V_D and protein binding still prevent removal by CRRT. Protein binding and the device filtration rate determine the rate of removal. A series of sieving coefficients is available that allows calculation of the amount of drug actually lost if the ultrafiltration flow rate is known.⁵ The sieving coefficient is the ratio of drug concentration in the ultrafiltrate to the pre-filter plasma water drug concentration. The closer the sieving coefficient is to 1.0, the more it passes across the filter. Again, there are few detailed studies of drug clearance with use of these methods, and clinicians must rely on estimates from hemodialysis, known physiochemical properties, and clinical response.

COMMON PRESCRIBING ISSUES IN CHRONIC KIDNEY DISEASE AND RENAL REPLACEMENT THERAPY

Anemia

Erythropoiesis-Stimulating Proteins

The pharmacokinetics of erythropoiesis-stimulating agents is not affected by renal function *per se*. However, as renal function decreases, their dose may need to be increased to account for reduced production of endogenous erythropoietin (EPO). Because of the absorption rate–limited increase in half-life of subcutaneous compared with intravenous EPO, epoetin alfa and beta are approximately 30% more efficient given subcutaneously than intravenously¹⁸ compared with no difference between subcutaneous and intravenous darbepoetin.¹⁹

Iron Therapy

Oral supplements may be sufficient in mild anemia in the early stages of CKD or in continuous ambulatory peritoneal dialysis patients who do not have the same degree of regular blood loss as hemodialysis patients do. Maximum absorption of oral iron occurs with frequent administration of small doses away from food. Gastrointestinal intolerance is a limiting complication, and

although this is reduced by administration with food, absorption is reduced. It is important to avoid interactions with drugs whose absorption is affected by oral iron. Patients with severe iron deficiency and those on hemodialysis often require regular intravenous rather than oral supplementation to maintain iron stores (see Chapter 79 for further discussion of anemia management).

Analgesics

Various analgesics (or their metabolites) undergo significant renal excretion or are nephrotoxic, and dose modification or avoidance is required.^{20,21} Fear of adverse effects often prevents the use of sufficient doses to manage pain appropriately. Adequate initial doses should be followed by careful assessment and titration to the minimal effective dose for the shortest period.

Acetaminophen (Paracetamol)

Despite suggestions that acetaminophen may be nephrotoxic, lack of platelet inhibition and gastrointestinal irritation makes it a safer base analgesic in CKD and RRT compared with NSAIDs and opioids. Acetaminophen is hepatically metabolized and does not require dose adjustment in renal impairment.

Opioid Analgesics

Opioids have primary metabolites with variable activity and dependence on renal excretion.^{22,23} Metabolite accumulation in renal impairment prolongs drug action and predisposes to central nervous system (CNS) toxicity (sedation, respiratory depression, confusion, hallucinations, and seizures), which is often difficult to distinguish from the symptoms of uremia. Regular opioid use in fluid-restricted patients can exacerbate constipation, particularly in peritoneal dialysis. Opioids should be used cautiously in renal impairment, giving adequate doses to establish control and titrating to the smallest effective dose for the shortest period.²⁴

There is wide variation in opioid pharmacokinetics and response even in those with normal renal function. Morphine is metabolized to two renally cleared active metabolites (morphine 3-glucuronide and morphine 6-glucuronide). Their accumulation in renal impairment may be responsible for CNS toxicity and respiratory depression or sedation.²⁵ Morphine is best avoided in renal impairment, but if it is essential, significant dose reduction is recommended. Meperidine (pethidine) is metabolized to a renally cleared metabolite (normeperidine) that can cause CNS toxicity (seizures, myoclonus, mental state changes, respiratory depression, and psychosis).²⁶ It too should be avoided in moderate to severe renal impairment. Dextropropoxyphene should also be avoided as it is metabolized to the renally cleared metabolite norpropoxyphene, which can accumulate and cause cardiac toxicity. Hydromorphone is metabolized to hydromorphone 3-glucuronide, which has minor activity and does not accumulate substantially. Buprenorphine is metabolized to relatively inactive metabolites, which are excreted in bile, and is relatively safe in renal impairment. Weaker opioids (codeine, dihydrocodeine, and hydrocodone) can still cause CNS and respiratory depression. They should be avoided or used cautiously in severe renal impairment. With appropriate titration, alfentanil, fentanyl, sufentanil, methadone, and oxycodone are relatively safer choices as they do not have significantly active metabolites. The partial opioid tramadol is metabolized to a renally cleared active metabolite, *O*-desmethyltramadol, whose half-life doubles in renal impairment and predispose to seizures, respiratory depression, and other CNS adverse effects. The maximum dose should be

lower in renal impairment. In opioid intoxication, naloxone may be used at normal dose to reverse the effect.

Nonsteroidal Anti-inflammatory Drugs

The most frequent nephrotoxic effect of NSAIDs is to cause acute renal impairment by preventing renal prostaglandin-mediated afferent arteriolar vasodilation (see Chapter 66). In healthy individuals, cyclooxygenase (COX) inhibition has little effect on renal function. Nephrotoxicity is more likely in those with a high renin state or renal hypoperfusion, in which renal prostaglandins are upregulated and play a supportive role in maintaining glomerular filtration through afferent arteriole dilation. Use of NSAIDs with ACE inhibitors, ARBs, diuretics, or antihypertensives significantly increases the potential for nephrotoxicity, and these combinations should be prescribed cautiously. When they are required, NSAIDs should be used at the lowest effective dose for the shortest period with monitoring of response and renal function. Increases in potassium, sodium, and fluid retention may also occur in renally impaired patients treated with NSAIDs.

Various NSAIDs cause a rare idiosyncratic nephritis that may present with acute interstitial nephritis or nephrotic syndrome with minimal change disease.²⁷ This form of renal failure typically has a protracted course. NSAIDs have also been associated with renal papillary necrosis and other pathologic changes during long-term administration. Selective COX-2 inhibition was initially thought to have less renal toxicity. However, because COX-2 is expressed in the kidney, COX-2-selective agents offer no advantage in renal toxicity over nonselective inhibitors.²⁸ The potential for cardiovascular complications of COX-2 inhibitors is also undesirable in renal patients at high risk for cardiovascular disease.

Drugs for Neuropathic Pain

Low-dose tricyclic antidepressants are used at normal doses in renal impairment, although patients may be more sensitive to anticholinergic side effects. Low-dose valproate and carbamazepine are used at normal doses. Extreme caution is required with gabapentin²⁹ and pregabalin³⁰ as they are extensively renally cleared and can cause significant CNS adverse effects (somnolence, lethargy, dizziness, and ataxia).

Antihistamines

Normal doses of sedating antihistamines can be used initially with titration based on response and typical cholinergic side effects to which renal patients may be more susceptible. Sedating antihistamines should be used cautiously in bladder outflow obstruction as they may cause or aggravate urinary frequency or retention. Newer, less sedating antihistamines are better tolerated. They have a wide therapeutic index, and accumulation rarely causes significant complications during short-term treatment. Cetirizine relies more on renal clearance, and dose reduction is suggested. Loratadine and desloratadine have active metabolites but are safe. Fexofenadine is safe; however, terfenadine should be avoided because of the risk of arrhythmias.

Anti-infective Agents

The kidneys excrete many anti-infectives in whole or in part, and dose reduction is often required in severe impairment or extended therapy. However, many others have a wide therapeutic index, and dose adjustment is clinically unnecessary despite their reliance on renal excretion. An important principle of anti-infective

dosing in renal impairment is to initiate effective drugs at sufficient doses. Excessive dose reductions may fail to achieve effective drug concentrations. Normal doses or doses larger than expected on the basis of renal function may be appropriate in treating less susceptible organisms and when drug distribution to the site of infection is reduced (e.g., meningitis). Loading doses equivalent to the dose in normal renal function may be appropriate to achieve therapeutic concentrations. More severe infection, particularly in severely immunocompromised patients, may require extended therapy. In urinary tract infection, if GFR is below 30 ml/min and the drug does not undergo tubular secretion, inadequate renal tract concentrations may result and systemic accumulation could lead to toxicity. Nitrofurantoin becomes ineffective in advanced renal impairment,³¹ and accumulation causes peripheral neuropathy. Anti-infective prescribing in urinary tract infection is discussed further in Chapter 51.

Antibacterials

Variations in pharmacokinetics of antibiotics with impaired renal function have significant impacts on clinical care.³²

Aminoglycosides

Aminoglycosides are extensively excreted unchanged by the kidneys and can cause nephrotoxicity and ototoxicity (see Chapter 66).³³ When use is essential, the total daily dose should be reduced, treatment courses kept to a minimum, and serum concentrations and renal function monitored closely. Because aminoglycosides undergo tubular secretion, high urine concentrations are achieved even in advanced renal impairment, and lower doses may be appropriate in uncomplicated urinary tract infections.

Aminoglycoside Dosing Schedules Despite short half-life (2 to 3 hours with normal renal function), aminoglycosides are usually given once daily rather than in divided daily doses for most indications other than endocarditis and in pregnancy. This is based on data showing that their action is dependent on “peak” concentration and that once-daily regimens have reduced toxicity. The required dose regimen depends on V_D and renal clearance. Dosing in renal impairment first involves reducing the “normal daily dose” (5 to 7 mg/kg for gentamicin and tobramycin or 15 mg/kg for amikacin) according to renal function (e.g., with 25% remaining renal function, reduce the total daily dose to 25% of normal). Because of their peak concentration-dependent activity, aminoglycosides should be administered at a minimum effective dose (≥ 2.5 mg/kg for gentamicin and tobramycin; ≥ 7.5 mg/kg for amikacin) to achieve target peak serum concentrations (>10 $\mu\text{g/ml}$ for gentamicin and tobramycin; >30 $\mu\text{g/ml}$ for amikacin). The reduced normal daily dose calculated might be lower than the minimum individual dose required to achieve target peak concentrations. If this is true (e.g., moderate to severe renal impairment), it may be necessary to administer the minimally effective dose at an extended interval (i.e., every 36 or 48 hours) rather than to reduce the size of the individual dose. Although commonly practiced, efficacy with longer dosing intervals (>48 hours) relies on a post-antibiotic effect, and it is uncertain whether this effect lasts for extended dosing schedules.

Aminoglycoside Concentration Monitoring Because of pharmacokinetic variability in infection and renal impairment as well as toxicity, monitoring is essential to guide aminoglycoside dosing. It is particularly important at the initiation of therapy or when significant changes occur in renal function or clinical

condition. Routine monitoring is not required for short treatment of less than 48 hours. Graphical methods that use a single-point concentration 6 to 14 hours after dosing are valid only with relatively normal renal function. They do not provide information on attainment of peak concentrations and are not recommended in renal impairment.

Trough concentrations can be measured to determine drug accumulation and to reduce the risk of toxicity. Trough samples must be interpreted in the context of the time after the dose when the sample was drawn. Trough monitoring does not provide information on the attainment of peak concentrations and may be below the limit of quantification of some assays. Some patients, especially those with severe sepsis and renal impairment, may have altered (usually higher) V_D , which results in lower peak concentrations. Measurement of peak concentrations (30 minutes after dosing) is the only certain way to determine if adequate peak concentrations are achieved and to assist in determining the size of subsequent doses. Combining peak and trough monitoring provides information on both V_D and clearance and can therefore be used to determine both the size of individual doses and the dosage interval. Provided the relationship between the time of dosing and blood sampling is known, simple dose modifications are made on first principle estimates (see earlier, [Methods of Dose Reduction](#)).

Carbapenems

Ertapenem, doripenem, imipenem,³⁴ and meropenem³⁵ are significantly excreted in urine but with appropriate dose modification can be used safely in CKD and transplantation. Imipenem can cause significant neurotoxicity (myoclonic activity, seizures, and confusion), especially when it is given in high dose to those with underlying CNS disorders or renal impairment. Meropenem and doripenem may be preferable as they appear less neurotoxic. Imipenem is inactivated by renal dehydropeptidase 1 and is combined with cilastatin to prevent this.

Cephalosporins

Despite being predominantly renally cleared, the relative safety of many cephalosporins means that normal doses of many agents can be used for most short-course therapies even in dialysis patients (e.g., ceftriaxone, cefaclor, and cephalexin). High-dose parenteral therapy and prolonged courses of some agents require dose reduction in severe impairment to prevent electrolyte disturbances and neurotoxicity. Reduction is suggested in severe impairment for cefepime,³⁶ cefotaxime,³⁷ ceftazidime,³⁸ cefoxitin, and cefazolin.³⁹ Therapeutic concentrations of cefazolin are maintained after doses of 20 mg/kg (~2 g) post dialysis three times per week.⁴⁰ Some cephalosporins give a creatinine-like reaction in assays based on the picrate method. This can falsely elevate serum creatinine and be mistaken for nephrotoxicity.⁴¹

Fluoroquinolones

Renal excretion is significant with ciprofloxacin, norfloxacin, and gatifloxacin, and doses of these agents should be halved if GFR is below 30 ml/min.^{42,43} Moxifloxacin is only 20% renally excreted, and dose reduction is not required. Norfloxacin is well secreted by the kidney and thus useful in urinary tract infections. Quinolones are generally well tolerated but have been known to cause CNS effects (headache, dizziness, insomnia, depression, restlessness, and tremors), interstitial nephritis, and crystalluria. Fluids should be encouraged (if tolerated) and excessively alkaline urine avoided to prevent crystalluria. Quinolones show reduced absorption when they are coadministered with

compounds containing metals such as magnesium, calcium, aluminum, and iron. As the timing of phosphate binders with meals is vital, quinolones should be administered away from meals and metallic phosphate binders.⁹

Glycopeptides

Glycopeptides (vancomycin and teicoplanin) are extensively renally excreted. Because of potential nephrotoxicity and ototoxicity, dose modification is essential even in mild to moderate renal impairment. Nephrotoxicity is greater in those with renal impairment, prolonged therapy, high doses, and concomitant nephrotoxins. Nephrotoxicity may be less common with teicoplanin. Ototoxicity may involve sensorineural deafness and tinnitus. Permanent deafness is more likely with previous auditory compromise or impaired renal function. If glycopeptides are essential, duration of therapy should be minimized with regular monitoring of serum concentrations and renal function. Glycopeptides demonstrate time-dependent antibacterial activity, so dosing should be repeated once serum concentrations fall below minimum inhibitory concentrations. In dialysis patients, single doses of vancomycin maintain therapeutic concentrations (>15 µg/ml) for 3 to 5 days.⁴⁴ Vancomycin is removed more extensively with high-flux than with low-flux dialysis membranes.

Lincosamides

Lincosamides (e.g., clindamycin and lincomycin) are relatively safe in renal impairment and transplantation and are not significantly excreted by the kidneys. A significant adverse effect is pseudomembranous colitis. If this occurs, the drug should be stopped. Fluid management and treatment with oral metronidazole or vancomycin are required to prevent hypovolemia and electrolyte disturbances.

Macrolides

Macrolides are mostly hepatically cleared, and dose modifications are usually not required even in end-stage renal disease (ESRD). However, dose reduction is required with high-dose or intravenous erythromycin,⁴⁵ which may prolong the QT interval and cause ototoxicity. Various macrolides are potent inhibitors of CYP3A4 and P-glycoprotein, so there may be significant interactions with and increased exposure to coadministered drugs that rely on CYP3A4- or P-glycoprotein-mediated absorption and metabolism (cyclosporine, tacrolimus, sirolimus, everolimus, and statins). Erythromycin and clarithromycin are the most significant inhibitors, and dose modification of the concomitant drug is required. Roxithromycin is a much weaker inhibitor and usually causes little or no clinically significant interactions. Azithromycin does not interact.

Penicillins

Most penicillins have a short half-life and are rapidly eliminated by filtration and secretion into urine. Many have a relatively wide therapeutic window, and so despite their significant renal clearance, many are used at normal dose for short courses of oral therapy. High-dose parenteral therapy or prolonged high-dose oral therapy may require dose reduction to prevent electrolyte disturbances and neurotoxicity in advanced renal failure. Because most penicillins exert little or no post-antibiotic effect, the amount of time above the minimum inhibitory concentration is more important than their maximum concentration. Severe reductions in frequency of administration are not advised. Dose reduction of ticarcillin-clavulanate⁴⁶ and piperacillin is advised in severe renal impairment.

Rifamycins

Rifamycins are mainly hepatically metabolized and used at normal dose even in severe renal impairment. Orange-red coloration of body fluids (e.g., urine and peritoneal dialysis fluid) is common. Infrequently, they cause hepatotoxicity and blood dyscrasias. Rifampin is a potent enzyme inducer and significantly increases metabolism of drugs, including immunosuppressants. Although it is structurally similar, rifabutin does not induce CYP450 enzymes to the same extent. If rifampin use is essential, the impact on the dose of concomitant drugs should be considered.

Tetracyclines

Tetracycline depends more on renal excretion than doxycycline and minocycline do. In renal impairment, tetracycline is anti-anabolic and can cause uremia, hyperphosphatemia, and metabolic acidosis; it may also aggravate preexisting renal failure.⁴⁷ Tetracycline should be avoided in renal impairment; however, doxycycline, minocycline, and tigecycline are not anti-anabolic and may be used as usual. Nephrotoxicity has occurred in association with “acute fatty liver” with high-dose tetracyclines. Degraded tetracycline (anhydro-4-epitetracycline) may result in renal tubular damage and a Fanconi-like syndrome.

Sulfonamides and Trimethoprim

Most sulfonamide use is accounted for by cotrimoxazole (sulfamethoxazole in a 5:1 combination with trimethoprim). This ratio was chosen to provide the optimal synergistic ratio of 20:1 in blood; however, the ratio in urine is closer to 1:1. Sulfonamides are eliminated by acetylation followed by renal excretion. Acetylated metabolites may cause crystalluria and tubular damage. Sulfamethoxazole and trimethoprim display similar renal excretion except at extremes of urine pH. Alkaline urine promotes sulfamethoxazole excretion, whereas acidic urine promotes trimethoprim excretion. Accumulation of both occurs in renal impairment,⁴⁸ and dose reduction is advisable except perhaps in the initial treatment of *Pneumocystis jiroveci* infection, in which the risk of toxicity is balanced against the seriousness of infection. Trimethoprim inhibits tubular secretion of creatinine, resulting in a reversible increase in serum creatinine⁴⁹ that can be misinterpreted as trimethoprim nephrotoxicity.

Other Antibiotics

Linezolid is used at normal dose. Metronidazole has a partially active, renally cleared metabolite, although only 15% of parent drug is renally cleared. It is usually given in usual doses or reduced to twice daily in dialysis.⁵⁰

Antimycobacterials

Antimycobacterial treatment (see also Chapter 52) in renal impairment and RRT requires dose modification according to renal function and avoidance of drug interactions.⁵¹ Of the first-line drugs, ethambutol is significantly renally cleared (80%) and has a prolonged half-life in renal impairment. Dose reduction is essential to avoid visual toxicity. Isoniazid, pyrazinamide, and rifampin-rifabutin can be given in usual doses. Rifampin can cause induction of hepatic enzymes and severe drug interactions with transplant immunosuppressants. Of the second-line agents, amikacin, kanamycin, streptomycin, capreomycin, and gatifloxacin are extensively renally cleared, are nephrotoxic, and require significant dose reduction.

Antifungals

Amphotericin

Amphotericin use is limited by nephrotoxicity (see Chapters 53 and 66). Nephrotoxicity with crystalline amphotericin may be minimized with pre-hydration and administration by continuous infusion. Newer liposomal formulations have fewer infusion-related problems and are less nephrotoxic⁵² but significantly more expensive. In maintenance dialysis patients who do not have potential for further clinically significant loss of renal function, liposomal or lipid preparations offer no major advantage except a lower incidence of infusion reactions. Oral amphotericin is not absorbed and does not contribute to nephrotoxicity.

Azole Antifungals

Most azole antifungals (ketoconazole, itraconazole, and voriconazole) are extensively metabolized and do not require dose reduction in renal impairment. Fluconazole,⁵³ however, is renally excreted; after an adequate loading dose, maintenance doses should be reduced in moderate to severe renal impairment, and it should be given after dialysis. Fluconazole is significantly excreted in urine and therefore the first choice in fungal urinary tract infections. The manufacturer recommends avoiding the intravenous formulation of voriconazole because of possible accumulation of the intravenous vehicle (sulfobutyl betadex sodium). Ketoconazole and itraconazole require an acidic environment for absorption. Given the widespread use of acid suppressants in renal impairment, this is a clinically important interaction. Voriconazole, ketoconazole, and itraconazole are potent inhibitors of CYP3A4 and P-glycoprotein, which are involved in the metabolism and absorption of a variety of drugs, including cyclosporine, tacrolimus, sirolimus, everolimus, and statins. A 2- to 10-fold reduction of the concomitant drug may be required with drug monitoring; however, the magnitude of interaction may restrict the ability to use the concomitant drug. Interactions between ketoconazole and calcineurin inhibitors or mTOR inhibitors have been exploited as a cost-reducing, “immunosuppressant-sparing” strategy. Increased exposure to statins (except pravastatin) increases the risk of rhabdomyolysis-induced renal impairment. Fluconazole is a weak enzyme inhibitor, and although caution should be exercised, the need for preemptive dose reduction of concomitant drugs is less certain. Topical azole antifungals including bifonazole, clotrimazole, econazole, ketoconazole (topical), tinidazole, and miconazole are minimally absorbed and do not cause interactions.

Other Antifungals

Absorption of nystatin from topical and oral preparations is minimal and safe in renal impairment. Terbinafine is hepatotoxic, and dose reduction of 50% is suggested in moderate to severe renal impairment. Griseofulvin and caspofungin can be given in usual doses. Flucytosine⁵⁴ is extensively renally cleared and requires dose reduction. All these agents do not interfere with CYP450 enzymes or P-glycoprotein.

Antivirals

Many antivirals (or their active metabolites) are extensively renally excreted and can cause nephrotoxicity (see Chapter 66).

Guanine Analogues

Acyclovir, its prodrug valacyclovir, and famciclovir⁵⁵ are extensively renally cleared and can crystallize in tubules, causing

obstructive uropathy. High concentrations also cause severe CNS toxicity (cerebral irritation, ataxia, and myoclonus). Strict dose reduction based on renal function is essential. Ganciclovir and its prodrug valganciclovir are extensively renally cleared,⁵⁶ and accumulation can lead to severe bone marrow toxicity. Dose reduction is essential even in mild renal impairment. All these agents are freely dialyzed and should be given after hemodialysis.

Hepatitis B and C

Pegylated interferon alfa-2a has a larger metabolic clearance than pegylated interferon alfa-2b,⁵⁷ which has higher renal clearance requiring dose reduction in renal impairment. Interferons can upregulate cell surface expression of class II histocompatibility antigens, which increases the potential for transplant rejection. Many oral antivirals used in hepatitis are extensively renally cleared, requiring avoidance or significant dose reduction. Ribavirin and its metabolites rely on renal excretion, and accumulation causes severe anemia; therefore, it is contraindicated if GFR is below 50 ml/min. Some have reported the use of ribavirin in dialysis with dose reduction and drug and blood count monitoring. Adefovir,⁵⁸ entecavir, lamivudine,⁵⁹ and telbivudine⁶⁰ are extensively renally excreted, and significant dose reduction is essential.

Neuraminidase Inhibitors

Oseltamivir is converted by hepatic esterases to its active metabolite, oseltamivir carboxylate, which is extensively (99%) renally cleared through filtration and secretion.⁶¹ The AUC is increased 10-fold in severe renal impairment (GFR <30 ml/min). Although it is well tolerated, a doubling of the dose interval is recommended with GFR below 30 ml/min. Despite intravenous doses showing significant reliance of zanamivir on renal clearance, dose modification is not clinically necessary because its absolute bioavailability from inhaled doses is approximately 2% and high intravenous doses are well tolerated.⁶¹

Other Antivirals

Cidofovir⁶² and foscarnet⁶³ are extensively renally cleared and require dose reduction in renal impairment. Both are nephrotoxic and require close monitoring of renal function and should be administered with hydration. Cidofovir is often administered with probenecid to slow renal secretion and to minimize nephrotoxicity.

Anticoagulants, Antiplatelet Agents, Thrombolytics, and Hemostatics

The risk of bleeding complications with these agents is increased in CKD and ESRD.^{64,65}

Unfractionated Heparin

Unfractionated heparin (UFH) clearance occurs by a rapid saturable mechanism of the endothelium and reticuloendothelial system and a slower nonsaturable mechanism through the kidneys.^{64,66} Half-life is slightly prolonged (1.5-fold) in renal impairment, especially at higher doses, when renal elimination is more significant. However, UFH is initially used at normal dose in renal impairment with titration based on activated partial thromboplastin time monitoring and response. In some centers, UFH is preferred in severe renal impairment because its effect is shorter and more easily measured and reversed.

Low-Molecular-Weight Heparin

Low-molecular-weight heparin (LMWH) relies more on renal clearance than UFH does. In moderate to severe renal impairment, LMWHs can accumulate, increasing the risk of serious bleeding.⁶⁷ Strong consideration should be given to use of UFH in this setting. Some studies suggest that enoxaparin dose does not need reduction in the first 48 hours of therapy and that tinzaparin is less likely to accumulate. If prolonged treatment doses of LMWHs are used, the dose should be reduced in severe renal impairment and, if possible, anti-Xa activity measured to guide therapy.

Other Parenteral Anticoagulants

Other anticoagulants that accumulate in renal impairment and that should be avoided or used with significant dose reduction include bivalirudin,⁶⁸ danaparoid,⁶⁹ fondaparinux,⁷⁰ lepirudin,⁷¹ ximelagatran,⁷² and melagatran.⁷² Argatroban may be used at normal dose.⁷³ Prostacyclin used to prevent platelet aggregation in hemodialysis circuits is rapidly hydrolyzed and not affected by renal impairment.

Oral Anticoagulants

The liver extensively metabolizes warfarin. In renal impairment, it is usually commenced at normal dose and titrated according to the international normalized ratio. Warfarin is highly protein bound, and in renal patients with hypoalbuminemia, there may be increased sensitivity to warfarin.⁷⁴ Similarly, hepatic metabolism may be altered in renal impairment, increasing sensitivity.⁷⁵

Antiplatelet Drugs

Commonly prescribed doses of oral antiplatelets (aspirin, clopidogrel, and dipyridamole) do not require initial adjustment for renal function. In acute coronary syndromes or percutaneous coronary intervention, moderate or severe renal dysfunction may influence the choice of intravenous glycoprotein IIb/IIIa inhibitors. Despite their efficacy in reduced renal function, eptifibatide⁷⁶ and tirofiban are renally excreted and have been associated with bleeding in this setting. Abciximab is cleared by platelet binding and is not associated with increased bleeding risk in renal impairment.

Thrombolytics

Streptokinase, anistreplase, and alteplase are used as normal in renal impairment, but the high risk of hemorrhage should be considered. Urokinase is also used to unclot dialysis catheters.

Hemostatics

Tranexamic acid requires dose reduction in moderate to severe renal impairment. Protamine and vitamin K are used as normal, as are fresh frozen plasma and whole blood in critical bleeding.

Diuretics

Most diuretics must reach the renal tubule lumen unbound to exert an effect.⁷⁷ Pharmacokinetic and pharmacodynamic properties of diuretics can change in proteinuria or renal impairment, usually causing a resistance to their effect. In excessive proteinuria, binding of diuretics to tubular protein can reduce their effectiveness.⁷⁷ Tubular secretion of various organic acid diuretics is reduced because of competition from uremic organic acids. The effects and use of diuretics are also discussed in Chapter 7. Diuretics must be used cautiously in AKI or renal hypoperfusion.

to avoid nephrotoxicity. Diuretic use in the immediate post-transplantation setting may increase urine flow in the native kidneys, giving a false appearance of transplant function. In addition to fluid status, diuretics can significantly alter serum electrolytes.

Thiazide Diuretics

Thiazide diuretics generally become ineffective as diuretics when GFR is below 30 ml/min, although they may augment the effectiveness of a loop diuretic and retain their antihypertensive effects. Metolazone can maintain efficacy at a lower GFR.

Loop Diuretics

Loop diuretics (furosemide, bumetanide, torsemide, and ethacrynic acid) remain effective at low GFR and are generally the preferred diuretics in renal impairment, although higher doses are usually required.

Potassium-Sparing Diuretics

Potassium-sparing diuretics are the least effective diuretics and are often contraindicated in moderate to severe renal impairment because of the risk of life-threatening hyperkalemia.

Antihypertensives

Hypertension is both a cause and consequence of renal disease and may be severe, requiring aggressive treatment with multiple drugs. Antihypertensives should be used cautiously according to clinical response to avoid renal hypoperfusion.⁷⁸ Hypotension from hemodialysis may require antihypertensives to be withheld or delayed on dialysis days.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Although various ARBs and the active metabolites of ACE inhibitors are renally excreted, they can be used effectively in CKD but should be initiated at low to moderate doses and titrated cautiously to clinical response, renal function, and serum potassium concentration. An increase in serum creatinine (up to 20% in the first 2 months in closely monitored patients) may be associated with blood pressure response. All ACE inhibitors and ARBs can cause acute renal impairment by inhibiting the angiotensin II-mediated homeostatic vasoconstriction of the efferent renal arteriole during renal hypoperfusion (e.g., dehydration, hypotension, blood loss, and infection) or preexisting renal impairment (see also Chapter 66). Nephrotoxicity is more likely with coadministration of drugs that reduce renal perfusion, including diuretics, antihypertensives, and NSAIDs.⁷⁹ Hyperkalemia is more likely to be provoked by ACE inhibitors and ARBs in those with renal impairment and those taking potassium-sparing diuretics or supplements, which should be used cautiously in this setting. Rarely, ACE inhibitors or ARBs can worsen anemia and increase the requirement for erythropoiesis-stimulating agents.

β -Blockers

Most β -blockers (carvedilol, labetalol, metoprolol, pindolol, and propranolol) are hepatically metabolized and used at conventional doses in CKD according to response. However, sotalol⁸⁰ and atenolol⁸¹ rely more on renal clearance. Sotalol dose reduction and titration are essential in renal impairment, although atenolol can be titrated up to normal doses even in dialysis patients. β -Blockers may slightly elevate serum potassium.

Calcium Channel Blockers

Pharmacokinetic parameters of calcium channel blockers are essentially unaltered in renal impairment. They are generally well tolerated and used in normal doses according to response. Dihydropyridine calcium channel blockers can cause significant edema, which can aggravate the edema of renal impairment. To varying extents, calcium channel blockers inhibit CYP3A4 and P-glycoprotein, causing increased absorption and reduced elimination of various substrate drugs, including cyclosporine, tacrolimus, sirolimus, and everolimus. Verapamil and diltiazem are moderately potent inhibitors, and dose modification and monitoring of the concomitant drug are required. This interaction has been exploited so that the calcium channel blocker is used as an immunosuppressant-sparing agent.⁸² Other calcium channel blockers do not usually cause clinically significant changes in concomitant drug concentrations, and dose modification is usually not required.

Other Antihypertensives

Methyldopa, clonidine, prazosin, terazosin, doxazosin, and minoxidil are renally cleared but can be initiated and titrated at conventional dosage. However, they are often associated with a higher incidence of adverse effects in renal impairment. α -Blockers cause profound orthostatic hypotension. Nitroprusside must be used cautiously because the toxic metabolite thiocyanate may accumulate in renal impairment but is hemodialyzable.⁸³

Antianginal Agents

Most antianginals (β -blockers, nitrates, calcium channel blockers, nicorandil, and perhexiline) can be used as normal, although atenolol may require initial dose reduction.

Antiarrhythmics

Various antiarrhythmics (digoxin, disopyramide, procainamide,⁸⁴ and sotalol⁸⁰) rely on renal excretion and require dose modification in renal impairment. Digoxin is most commonly used, and because of its significant reliance on renal excretion and narrow therapeutic window, dose reduction is essential even in mild impairment. Because of reduced tissue protein binding and V_D , some physicians use a smaller loading dose of digoxin than in normal renal function. Cautious monitoring and titration should be exercised to prevent accumulation and further toxicity, which may present as the arrhythmia the drug was intended to correct. When it is possible, monitoring of antiarrhythmic drug concentrations and the electrocardiogram is recommended. Other agents (amiodarone, flecainide, metoprolol, mexiletine, and verapamil) are used at normal doses.

Lipid-Lowering Agents

Bile Acid-Binding Resins

Bile acid-binding resins are now rarely used. The large fluid volumes required to administer them can limit their use in renal impairment. They can interfere with absorption and enterohepatic recirculation of various drugs, including mycophenolate.

Statins

Statins (HMG-CoA reductase inhibitors) can be used effectively in renal impairment and transplantation.⁸⁵ Most are extensively metabolized to products with varying activity; however, normal doses may be used in the first instance and then titrated to target

cholesterol values. Rhabdomyolysis with acute renal impairment can occur with statins, although the risk does not appear to be greatly increased with renal impairment. The risk increases with use of fibrates and drugs that inhibit the CYP3A4 metabolism of statins. Patients commencing therapy should have lipids, renal function, and creatine kinase monitored regularly.

Fibrates

Fenofibrate but not gemfibrozil is extensively renally excreted, and dose reduction is required in moderate to severe impairment. Combination of statins and fibrates significantly increases the risk of rhabdomyolysis and should be used only when benefits outweigh risks and with monitoring for muscle symptoms, creatine kinase, and alanine aminotransferase.

Diabetes

The kidney plays an important role in insulin metabolism,⁸⁶ and thus renal impairment influences glycemic control. Diabetes is also common after renal transplantation due to resumption of insulin metabolism by the functioning transplant and the effect of drugs (tacrolimus and corticosteroids). Various antidiabetic drugs (or their metabolites) depend on renal excretion, and accumulation in renal impairment can cause adverse effects.⁸⁷ Patients with renal impairment are therefore at increased risk for hypoglycemia, and drugs should be initiated and titrated cautiously.⁸⁸ Management of diabetes in CKD is discussed in Chapter 31.

Diabetes Management in Peritoneal Dialysis

Peritoneal dialysis patients may have higher antihyperglycemic requirements because of the glucose load in peritoneal dialysis fluid. If intraperitoneal insulin is used, dosing may vary from intravenous requirements. Icodextrin solutions can significantly interfere with blood glucose monitoring as a result of metabolites (maltose, maltotriose, or maltotetraose), which falsely elevate blood glucose readings from monitors that use the enzyme glucose dehydrogenase pyrroloquinoline quinone. A glucose-specific test strip is required to avoid interference.

Biguanides

Metformin is almost entirely excreted unchanged in urine, and accumulation in renal impairment can contribute to severe or fatal lactic acidosis (see Chapter 31).⁸⁹ Metformin should be temporarily discontinued in situations known to increase the risk of lactic acidosis or to reduce renal function (e.g., acute tissue hypoxia, dehydration, serious infection or trauma, and 24 to 48 hours before anticipated surgery or use of iodinated radiocontrast media). Although metformin is not usually recommended if GFR is below 60 mL/min and certainly below 30 mL/min, low-dose protocols may be considered in a specialized setting. Nevertheless, stability of a patient with renal impairment receiving low-dose metformin does not abolish the risk of lactic acidosis. Lactic acidosis has occurred with doses as low as 500 mg/day, and any acute deterioration in renal function can result in reduced drug clearance at any time. Patients on this regimen should be advised to seek early medical advice in any cases of acute deterioration in health.

Insulin

As renal function decreases, insulin clearance decreases (see Chapter 31). Uremia, however, can cause peripheral resistance to insulin, requiring increased doses. Most insulin regimens can be used in CKD or transplantation with cautious titration

and monitoring. Theoretically, insulin glargine is preferable to insulin detemir in renal impairment because the latter is highly bound to serum albumin, and in patients with decreased or unstable serum albumin, a higher free fraction may occur.

Meglitinides

The non-sulfonylurea insulin secretagogues repaglinide and nateglinide can be used in renal failure without dose adjustment.

Sulfonylureas

Sulfonylureas are metabolized and some (glibenclamide and glimepiride) have active, renally excreted metabolites. In moderate to severe renal impairment, hypoglycemic risk is increased.⁹⁰ These agents should be initiated at low dose and titrated to response. Gliclazide and glipizide are preferable in renal impairment as they do not have active metabolites. Regardless of which agent is used, the effect of sulfonylureas may still be increased because the insulin released by the drug will itself have a prolonged duration of action in renal impairment.

Thiazolidinediones

Thiazolidinediones are extensively metabolized and excreted in bile. Their pharmacokinetics are not significantly altered by renal impairment and in fact show reduced exposure, possibly due to reduced protein binding.^{91,92} However, they can cause fluid retention and edema, exacerbating the difficulties of fluid management and heart failure.⁸⁷ Thiazolidinediones have been associated with dilutional anemia due to an increase in plasma volume, which may complicate management of renal anemia.

Drugs for Thyroid Disorders

Thyroid hormones generally do not require dose alteration in CKD.⁹³ Doses should be initiated and titrated to thyroid-stimulating hormone levels and clinical effect. In circulation, thyroxine (T₄) is 99.98% protein bound (0.02% free) and triiodothyronine (T₃) is 99.8% bound (0.2% free). T₃ and T₄ bind partially, in slightly different proportions, to three different plasma proteins: thyroid-binding globulin, thyroid-binding prealbumin, and albumin. In protein-deficient states (e.g., nephrotic syndrome), there is the possibility of transient or permanent changes in thyroid hormone protein binding that may alter the free fraction of T₃ and T₄, leading to transient toxicity. Uremic toxins can also inhibit enzymes associated with conversion of T₄ to T₃. Oral absorption of thyroid hormones is affected by coadministration with metallic phosphate binders and iron, so thyroid hormone supplements should be dosed away from binders. Hyperthyroid or hypothyroid states may alter the metabolism of drugs, including immunosuppressants. Achieving a euthyroid state helps avoid complications of altered drug metabolism. Euthyroid patients with CKD may have abnormal thyroid function test results, possibly due to decreased peripheral conversion of T₄ to T₃, decreased clearance of reverse T₃ generated from T₄, or decreased binding of thyroid hormones to proteins. Anti-thyroid drugs can be used at usual doses.

Mineral and Bone Disorders

Phosphate Binders

Phosphate binders should be taken with meals for maximal efficacy. Patients can be instructed to tailor phosphate binder intake to the phosphate content and frequency of meals. Dosing is not

affected by renal function except that reducing function increases the need for phosphate binders. Dosing is based on phosphate levels and the need to avoid biochemical abnormalities (see Chapter 81). Acid suppression may reduce the effectiveness of phosphate binders by inhibiting hydrolysis of metallic ions in the gut. Phosphate binders may reduce gastrointestinal absorption of drugs, including thyroid hormones, fluoroquinolones, tetracyclines, digoxin, and immunosuppressants.

Vitamin D

In renal impairment, inability of the kidneys to activate 25-hydroxycholecalciferol to calcitriol may produce relative vitamin D deficiency and hypocalcemia. In combination with hyperphosphatemia, this may trigger secondary hyperparathyroidism (see Chapter 81). For this reason, active 1,25 vitamin D is often preferred to the less active precursors D₂ and D₃, or a combination is sometimes given. Hypercalcemia is the most common and dose-limiting toxicity of vitamin D (see Chapter 10). Patients treated with ergocalciferol (D₂) and cholecalciferol (D₃) at physiologic doses (e.g., ≤2,000 IU/day) are not usually at risk for hypercalcemia. The risk for and magnitude of hypercalcemia are significantly higher with active forms of vitamin D, calcitriol or alfacalcidol; however, hypercalcemic episodes may be shorter and easier to treat than with longer acting substances. Hypercalcemia is exacerbated by concurrent use of high-dose calcium salts (e.g., used as phosphate binders). Calcitriol also stimulates gastrointestinal absorption of phosphate, thus worsening the hyperphosphatemia of CKD.

Calcimimetics

Cinacalcet (see Chapter 81) dosing is independent of renal function except that progressive renal impairment exacerbates secondary hyperparathyroidism. When it is possible, cinacalcet should be dosed with the evening meal to increase absorption and ensure that morning parathyroid hormone blood samples are drawn at least 12 hours after dosing.

Dyspepsia, Gastroesophageal Reflux Disease, and Peptic Ulcers

Proton pump inhibitors and H₂ receptor blockers are commonly used in CKD (see Chapter 83). Acid suppression may reduce the effectiveness of phosphate binders by inhibiting the release of free metallic ions in the gastrointestinal tract.

Antacids

Alginates, magnesium trisilicate, and sodium bicarbonate are useful for symptom control but have high sodium content, which exacerbates hypertension and fluid status. Magnesium and aluminum salts can reduce the absorption of mycophenolate.

H₂ Antagonists

Most H₂ antagonists are renally cleared but relatively safe; in practice, most clinicians do not reduce their dose.⁹⁴ Protein binding and *V_D* are unaltered; however, the bioavailability of nizatidine is reduced in renal impairment. Accumulation of cimetidine⁹⁵ produces CNS effects, and it also causes significant interactions through the CYP450 system and falsely elevates serum creatinine.⁹⁶ It should be avoided in renal impairment.

Proton Pump Inhibitors

Proton pump inhibitors are generally safe and well tolerated in renal impairment and have a wide therapeutic index. Proton

pump inhibitors have rarely been associated with interstitial nephritis.⁹⁷

Antiemetics

Dopamine Antagonists

Domperidone, metoclopramide, and prochlorperazine are not significantly renally cleared and can be used in CKD; however, extrapyramidal and CNS effects may be more prevalent, especially in high dose. Dosing should be cautiously titrated to effect. Domperidone does not cross the blood-brain barrier and may be preferable for long-term management. Metoclopramide and domperidone increase gastric emptying, which may alter drug pharmacokinetics.

5-HT₃ Antagonists

Most 5-HT₃ antagonists are minimally excreted in urine with a wide therapeutic window. Dolasetron, granisetron, ondansetron, and tropisetron are safe, and dose modification is not required.

Aperients and Laxatives

Common low-potency agents including docusate, bisacodyl, glycerin, lactulose, liquid paraffin, senna, and sorbitol may be used for acute or chronic constipation in renal impairment. Normal doses should be titrated to effect while avoiding significant dehydration, fluid shifts, or electrolyte disturbances. High-potency laxatives and bowel preparations should be used cautiously. They can cause significant fluid and electrolyte disturbances, especially in susceptible renal patients. Preparations containing high amounts of phosphate should be avoided. Despite the large fluid volumes required for administration, iso-osmotic laxatives may be used for bowel preparation in renal impairment and dialysis.

Antidiarrheals

Opioids or their derivatives should be used with the same caution as when they are used as analgesics. Loperamide and diphenoxylate-atropine can be given in usual dose.

Antiobesity Drugs

Drug therapy for obesity can prevent absorption of intestinal material or suppress appetite, which may cause nutrient deficiency. Sibutramine is used without modification, although it can increase heart rate and blood pressure. Sympathomimetics can cause CNS stimulation. Laxative and diuretic use is discouraged as they predispose to fluid and electrolyte disorders and renal hypoperfusion.

Drugs for Erectile Dysfunction

Phosphodiesterase-5 Inhibitors

The AUCs of sildenafil (twofold), tadalafil (fourfold), and vardenafil (20% to 30%) are increased in severe renal impairment despite minimal dependence on renal excretion.⁹⁸ However, provided relevant cardiovascular and drug contraindications are excluded, phosphodiesterase-5 inhibitors can be used in renal impairment and transplantation. They should be initiated at low dose and titrated to response. In renal impairment, shorter acting agents (sildenafil and vardenafil) may be preferable. Vardenafil can prolong the QT interval.

Intracavernosal Therapy

Drugs given directly by intracavernosal injection do not achieve significant concentrations in the systemic circulation and can be used in renal impairment.

Immunosuppressants

Immunosuppression in renal transplantation as well as its adverse effects is discussed in Chapters 97 and 103. In organ transplantation, immunosuppressants from different classes are combined to increase efficacy and to minimize adverse effects. Initial and maintenance doses in any individual are highly variable and depend on local protocol, concomitant therapy, risk of rejection, serum drug concentrations, and response. Immunosuppression is required for the life of the transplant and should never be withheld except in exceptional circumstance (life-threatening infection or malignant disease). Regimens should preferably be limited to twice daily, spread at convenient times about 12 hours apart. In practice, the precise timing of doses or intake relative to time and food is not as important as consistency in relation to time and food. Patients should take their medications consistently, and doses can be titrated to levels and response. Most immunosuppressants are cleared by hepatic metabolism and require little or no dose modification based on altered drug excretion in renal impairment.

Immunosuppressants are prone to a range of significant drug interactions. As the consequences of altered drug action are so great, all changes to drug regimens in transplant patients should be considered for their potential to interact. Significant interactions can also occur with “natural” or “herbal” medicines (e.g., St. John’s Wort; see also Chapter 74). If these products are deemed essential, it is advisable to monitor response, renal function, blood counts, and serum drug concentrations regularly. Therapeutic monitoring is recommended for several immunosuppressants⁹⁹ (tacrolimus, cyclosporine, everolimus, sirolimus, and mycophenolate). Target levels should be interpreted in the context of the patient’s response, immunosuppressive regimen, time after transplantation, and assay methodology.¹⁰⁰ Pharmacokinetics may vary in relation to food (e.g., tacrolimus) or concomitant drugs (e.g., sirolimus with or without cyclosporine), so blood sampling should aim to reflect the patient’s usual routine.

Calcineurin Inhibitors

Calcineurin inhibitors are extensively metabolized to numerous inactive metabolites, and initial dosing is not adjusted on the basis of altered exposure in renal impairment. The major toxicity of calcineurin inhibitors is nephrotoxicity (acute and chronic),¹⁰¹ and regular assessment of renal function is essential. Nephrotoxicity may increase with concurrent use of mTOR inhibitors (sirolimus and everolimus). Early detection of calcineurin inhibitor nephrotoxicity on biopsy assists in planning maintenance therapy (see Chapters 97 and 103). Because of nephrotoxicity, lower doses or temporary withdrawal may be used when calcineurin inhibitors have caused or are likely to cause nephrotoxicity (e.g., delayed graft function).

Calcineurin inhibitors are substrates of P-glycoprotein and CYP3A4. Drugs that inhibit or compete as substrates for these enzymes can increase absorption and reduce metabolism of calcineurin inhibitors, causing increased serum concentrations and adverse effects. Drugs that induce these enzymes can reduce absorption and increase metabolism of calcineurin inhibitors, causing reduced serum concentrations, and increase the risk of

rejection (see Fig. 73.11). Cyclosporine but not tacrolimus interferes with the enterohepatic recirculation of mycophenolate, and so the mycophenolate dose may need to be higher if it is coadministered with cyclosporine compared with the use of mycophenolate alone or with other immunosuppressants. Tacrolimus trough concentrations (C_0) show good correlation with drug exposure (AUC) and are used to monitor therapy. Debate remains about the optimal method of monitoring cyclosporine. Clinically, a combination of C_0 (trough), C_2 (concentration 2 hours post dose), and AUC_{0-4} (multipoint area under curve, 0 to 4 hours) are used. Different assay methodologies (high-performance liquid chromatography [HPLC], immunoassays) have differing ability to detect parent compound from metabolites. Specific HPLC methods are recommended, and results from different laboratories may not be interchangeable.¹⁰⁰

Corticosteroids

Corticosteroids are predominantly cleared by hepatic metabolism to inactive metabolites. Dose modification based on impaired renal function is not required.

Antiproliferative and Cytotoxic Agents

Various antiproliferatives and cytotoxics are used to prevent rejection (azathioprine and mycophenolate) and in autoimmune and inflammatory disorders (azathioprine, cyclophosphamide, chlorambucil, methotrexate, and mycophenolate). Their primary dose-limiting toxicity is bone marrow suppression, which is exacerbated by combined use with other bone marrow suppressants (e.g., ganciclovir, cotrimoxazole, and mTOR inhibitors). Regular blood monitoring is needed to guide dosing in renal impairment and transplantation.

Methotrexate relies significantly on renal clearance and should be avoided or used cautiously at a significantly reduced dose. It can also cause obstructive uropathy. Renal clearance is significant with cyclophosphamide¹⁰² (which also causes hemorrhagic cystitis) and chlorambucil, and dose modification is required. Accumulation of mycophenolate metabolites in severe renal impairment predisposes to adverse effects. Allopurinol significantly interferes with the metabolism of the active metabolite of azathioprine (6-mercaptopurine), and co-prescription can lead to life-threatening bone marrow suppression. The combination should be avoided by exchanging azathioprine with mycophenolate or by significant (75%) dose reduction of azathioprine or mercaptopurine.

mTOR Inhibitors

Although not nephrotoxic when they are used alone, mTOR inhibitors (sirolimus, everolimus) can potentiate the nephrotoxicity of calcineurin inhibitors, particularly in ongoing maintenance therapy. mTOR inhibitors are almost entirely hepatically metabolized to essentially inactive metabolites. Dosing is independent of renal function and based on clinical situation, serum drug levels, and specific toxicities (especially hematologic and lipids). mTOR inhibitors are substrates of CYP3A4 and P-glycoprotein. Drugs that inhibit or compete as substrates for these enzymes can increase absorption and reduce metabolism of mTOR inhibitors, causing increased blood concentrations and adverse effects. Drugs that induce these enzymes can reduce absorption and increase metabolism of mTORs and consequently reduce serum concentrations and increase the risk of rejection (see Fig. 73.11). Bone marrow toxicity (neutropenia, anemia, and thrombocytopenia) is increased when they are used in combination with other myelosuppressants (azathioprine,

mycophenolate, ganciclovir, and cotrimoxazole). Trough levels show good correlation with drug exposure (AUC) and are used to monitor mTOR inhibitor therapy. Different assay methodologies (HPLC versus immunoassays) vary in their ability to detect parent drug from metabolites. Specific HPLC methods are recommended, and results from different laboratories or methods may not be interchangeable.

Immunosuppressant Antibodies

Biologic agents used for immunosuppression include T cell-depleting antibodies (antithymocyte globulin, anti-CD3 antibodies [OKT3]), anti-interleukin-2 receptor (CD25) antibodies (basiliximab and daclizumab), and B cell-depleting antibodies (rituximab). Their use and adverse effects are discussed in Chapter 97. Dosing of these agents is independent of renal function, and they should be administered after concurrent plasma exchange¹⁰³ to avoid drug removal. They are not removed by hemodialysis.

Musculoskeletal Drugs

Nonsteroidal Anti-Inflammatory Drugs

NSAIDs can cause significant nephrotoxicity (see Chapter 66) and should be avoided or used with extreme caution in patients with renal impairment and in transplantation.

Miscellaneous Arthritis Drugs

Gold salts and penicillamine¹⁰⁴ are now rarely used for rheumatoid arthritis; both were associated with nephrotic syndrome due to membranous nephropathy. Glucosamine and fish oil have been used without apparent increase in toxicity in renal impairment or transplantation.

Gout and Hyperuricemia

Gout is highly prevalent in renal impairment, and treatment is complicated by several factors. In acute therapy, short courses of oral corticosteroids are safe and often preferable in renal impairment and transplantation and avoid the need for NSAIDs. Colchicine¹⁰⁵ accumulation in renal impairment may cause diarrhea and hypoperfusion-induced renal impairment as well as myelosuppression. It is best avoided or used at lower doses with careful attention to avoid gastrointestinal and hematologic toxicity. In maintenance therapy, allopurinol is effective but should initially be dose reduced in moderate to severe renal impairment because of formation of a renally cleared active metabolite (oxypurinol).¹⁰⁶ Despite this, some ESRD patients tolerate normal doses. Allopurinol significantly interacts with azathioprine, with a risk of severe myelosuppression. If the combination is unavoidable, the dose of azathioprine should be reduced to 75% and blood counts monitored carefully. Uricosuric agents (e.g., probenecid) inhibit secretion of acids in the proximal tubule and prevent reabsorption of uric acid from the tubular lumen. They often become ineffective with diminishing renal function and are best avoided if the GFR is below 40 ml/min unless clear benefit is demonstrated.¹⁰⁷ Probenecid also interferes with the tubular secretion of many drugs, causing interactions.

Bisphosphonates

Bisphosphonates are extensively excreted in urine. The fraction not excreted is incorporated into bone, from which it slowly dissociates. In renal impairment, impaired clearance of absorbed drug may increase the fraction available for incorporation into bone and thus the risk of adynamic bone disease. Their long

terminal elimination half-life reflects rate-limiting dissociation from bone and may not significantly be altered in renal impairment. Oral bisphosphonates appear to be safe in stage 2 to stage 3 CKD.¹⁰⁸ Their safety in CKD stages 4 and 5 is less well established; they may worsen low bone turnover in adynamic bone disease. Rapid administration of intravenous bisphosphonates (pamidronate and zoledronic acid¹⁰⁹) without hydration has been associated with acute nephrotoxicity. Intravenous preparations should be administered slowly with hydration, and renal function should be assessed regularly. Oral bisphosphonate dosing may be complicated by the volumes of fluid recommended for administration. In addition, many patients with renal impairment are taking calcium-based phosphate binders or supplements that impair the absorption of oral bisphosphonates. Once-weekly dosing given at least 30 minutes before food and any calcium-based medications or supplements is preferable to daily doses. This reduces the total weekly fluid load required to administer the tablets and helps ensure absorption.

Antiepileptics

Renally impaired patients may be more prone to seizures (e.g., uremic encephalopathy and dialysis disequilibrium syndrome) and to the CNS effects of antiepileptics. Some antiepileptics rely on renal excretion, and dose modification is essential. Some antiepileptics (barbiturates, phenytoin, and carbamazepine) are strong inducers of drug-metabolizing enzymes. Coadministration with drugs reliant on hepatic metabolism (e.g., immunosuppressants) can reduce exposure and efficacy of the concomitant drug. Therapeutic drug monitoring is available for many antiepileptics and should be used to guide dosing.

Barbiturates

Phenobarbitone and primidone are now rarely used. Significant amounts of active drug and metabolites are excreted in urine, necessitating lower initial doses. Patients with renal impairment may be more prone to CNS adverse effects, such as sedation. Barbiturates are potent enzyme inducers, and care must be taken to account for drug interactions, particularly in transplantation. In renal impairment, barbiturates should be titrated cautiously to response, adverse effects, and drug concentrations.

Benzodiazepines

See later, **Psychotropic Drugs**.

Carbamazepine

Carbamazepine is initially dosed as normal in renal impairment and titrated to response and blood concentrations. It is a potent enzyme inducer, and care must be taken to account for important drug interactions, particularly in the transplant setting.

Gabapentin and Pregabalin

Extreme caution is advised with pregabalin³⁰ and gabapentin²⁹ as they are almost completely renally cleared. Accumulation in renal impairment causes significant CNS adverse effects (somnolence, lethargy, dizziness, and ataxia). They should be avoided or used extremely cautiously at significantly lower doses even in mild to moderate renal impairment. Both are freely dialyzable, which can be beneficial in overdose.

Phenytoin

Caution should be exercised with phenytoin in renal impairment because of its erratic absorption, saturable metabolism, nonlinear

pharmacokinetics, reduced protein binding, and increased V_D . The concentration of free drug may be higher than in those with normal renal function; because most laboratories measure total drug concentration, a low serum total phenytoin level in renal impairment should not be mistaken as subtherapeutic. Nystagmus, cerebellar ataxia, and seizures can occur in overdose, and small dose increases may result in disproportionate increases in serum concentrations. Physical findings such as nystagmus are helpful in deciding not to increase the dose. Cautious titration based on effect and monitoring of free plasma concentration is advised. Phenytoin is a potent enzyme-inducing agent, and care must be taken to account for drug interactions, especially in the transplant setting.

Other Antiepileptics

Levetiracetam, topiramate, and vigabatrin undergo significant renal excretion, and dose modification is required in renal impairment. Valproate and lamotrigine are not significantly renally excreted and do not cause enzyme induction or inhibition. They are initiated as normal in renal impairment and transplantation with titration according to concentration and effect. Protein binding changes can increase the free fraction of valproic acid, predisposing to increased responsiveness.

Antiparkinsonian Drugs

In addition to their use in Parkinson's disease and hyperprolactinemia disorders, dopaminergic drugs are used to treat restless legs and other limb movement disorders in renal impairment. Most are hepatically cleared and safe in renal impairment and transplantation, although dopaminergic agents may exacerbate postural hypotension. Amantadine¹¹⁰ is highly dependent on renal excretion, and dose modification is essential.

Antimigraine Drugs

Simple analgesics (acetaminophen) are used as normal, although aspirin should be avoided at therapeutic doses and opioids used cautiously (see [Analgesics](#)). NSAIDs are best avoided because of potential nephrotoxicity. 5-HT₁ agonists are effective in renal impairment and transplantation. Naratriptan relies the most on renal excretion (50%), and a lower maximum dose is recommended. Sumatriptan and zolmitriptan are preferred as they are less dependent on renal excretion.

Psychotropic Drugs

Most psychotropics are fat soluble, are nondialyzable, undergo significant hepatic metabolism, and are excreted as inactive compounds. Even so, patients with renal impairment are often more susceptible to common adverse effects (especially CNS effects).^{111,112} Consequently, slow titration and dose modifications are required. Adverse effects are not easily distinguished from symptoms of uremia. Despite being metabolized extensively by CYP450 enzymes, very few psychotropics cause clinically significant inhibition or induction of CYP3A4.

Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors are extensively metabolized by the liver. Although they are less commonly used in current practice, normal doses of reversible monoamine oxidase inhibitors (moclobemide) are preferred, and these can be titrated cautiously up to full doses in renal impairment. Monoamine oxidase

inhibitors can cause peripheral edema, which is not usually associated with fluid retention and is unresponsive to diuretics. Prostatic hypertrophy and urinary retention may also occur.

Serotonin-Specific Reuptake Inhibitors

Serotonin-specific reuptake inhibitors (SSRIs) have become the most common drugs for treating depression in renal impairment and transplantation. Most are extensively metabolized to compounds without significant SSRI activity.¹¹³ Normal doses of most SSRIs (citalopram, fluvoxamine, paroxetine, and sertraline) can be used with cautious dose titration. Fluoxetine is metabolized to an active metabolite (norfluoxetine), but single- and multiple-dose studies have shown little change in pharmacokinetics even in dialysis patients.¹¹⁴ Patients with renal impairment may be more prone to the CNS toxicity of SSRIs and serotonin syndrome. SSRIs can cause the syndrome of inappropriate antidiuretic hormone secretion and platelet aggregation or hemorrhagic complications, which theoretically increases the risk of bleeding in uremic patients who are already prone to bleeding complications. SSRIs vary in their potential to inhibit CYP450 enzymes, with citalopram having the lowest capacity. Although most SSRIs have some inhibitory effect on CYP3A4, this is usually not significant. Fluoxetine and fluvoxamine are more likely to interact than citalopram and sertraline, but all can be used in patients taking immunosuppressants. Cinacalcet can cause significant inhibition of CYP2D6-mediated metabolism of SSRIs and perhexiline. This may increase the possibility of serotonin syndrome or perhexiline toxicity.

Tricyclic Antidepressants

Tricyclic antidepressants are now infrequently used for depression but more for neuropathic pain and their anticholinergic properties in urinary tract disorders. They are predominantly metabolized in the liver to metabolites with varying activity. Patients with renal impairment may be more prone to the common anticholinergic adverse effects, particularly urinary retention, orthostatic hypotension, confusion, and sedation.¹¹⁵ Obstructive uropathy can occur from the anticholinergic properties. Cautious initial dosing and titration of tricyclic antidepressants are recommended. Depending on response, many agents can be used at up to normal or maximal doses in renal impairment.

Other Antidepressants

Venlafaxine dose should be initially reduced in severe renal impairment because of reduced clearance of the active metabolite, *O*-desmethylvenlafaxine.¹¹⁶ Nefazodone is used at normal dose.

Antipsychotics

Conventional antipsychotics cause a variety of side effects to which patients with renal impairment may be susceptible (sedation, confusion, and postural hypotension). Caution is advised for atypical antipsychotics that prolong the QT interval (e.g., pimozide, thioridazine, mesoridazine, droperidol, and ziprasidone). Newer atypical agents are more commonly used and better tolerated. Clozapine, olanzapine, quetiapine, and aripiprazole are commenced at normal doses in renal impairment and titrated to response. Risperidone¹¹⁷ and its active metabolite, 9-hydroxyrisperidone, are renally excreted, and clearance is reduced by 60% in severe renal impairment. Lithium is filtered and reabsorbed mainly in the proximal tubules. It is extensively renally excreted and accumulates even in mild renal impairment, causing toxicity, and it should be avoided if possible. If use is essential, the dose must be reduced with monitoring of plasma concentrations.

In hyponatremic patients, tubular reabsorption of lithium is increased, leading to increased plasma concentrations and toxicity. NSAID co-prescription may also increase toxicity. Hemodialysis is efficient in removal of lithium and can be used in overdose; however, multiple dialysis treatments are usually required as plasma concentrations rebound soon after hemodialysis. Chronic lithium nephrotoxicity is discussed further in Chapter 62.

Benzodiazepines

Benzodiazepines are extensively metabolized by the liver to a range of active and inactive metabolites. Enhanced CNS toxicity, especially sedation, is the main concern in renal patients.^{118,119} Because of the potential for accumulation, chronic use should be discouraged when possible. Short-acting benzodiazepines are preferred, and dosing should be titrated cautiously according to response. The dose of midazolam should be reduced because of changes in plasma protein binding. Hemoperfusion and dialysis are not useful in benzodiazepine intoxication. Flumazenil may be used as normal in cases of benzodiazepine overdose.

Vaccines

Live vaccines (Bacille Calmette-Guérin, oral poliovirus, rubella, typhoid, yellow fever, and varicella) in immunosuppressed transplant patients are contraindicated because of the potential for causing disease. Attenuated vaccines (diphtheria-tetanus, hepatitis B, influenza, meningococcal, and pneumococcal) may be used; however, the immune reaction required for vaccine response may be diminished in immunocompromised individuals, and appropriate protection may not occur. Hepatitis B may need more doses for seroconversion to be achieved in hemodialysis patients. Immunization should preferably occur at least 1 month before initiation of immunosuppression. After transplantation, the immune response may be inadequate for at least 6 to 8 months, meaning that vaccination should be withheld until then.¹²⁰ Immunization in renal impairment is discussed further in Chapter 80.

Vitamin Supplementation

Patients with renal impairment may become vitamin deficient as a result of poor dietary intake and the effect of dialysis on removal of water-soluble vitamins. Administration of vitamin supplements (B, C, and folic acid) is recommended after dialysis.

Herbal and Over-the-Counter Medicines and the Kidney

Mark S. Segal, Xueqing Yu

In recent years, the use of herbal medicines and dietary supplements to promote health and to treat various chronic diseases has increased globally. An estimated one third of adults in developed countries and more than 80% of the population in many developing countries are using herbal and folk medicines to promote health and to manage common maladies such as cold, hay fever, inflammation, heart disease, indigestion, constipation, liver cirrhosis, cancer, acquired immunodeficiency syndrome, diabetes, and central nervous system diseases.¹ In Africa, up to 80% of the population depends on traditional medicine for primary health care; in China, herbal preparations account for up to 50% of the total consumption of pharmaceutical agents. There has been a surge in the popularity of herbal medicine in the West. For instance, the size of the U.S. herbal medicine market has increased from U.S. \$1.6 billion in 1994 to U.S. \$3.9 billion in 1998, and the proportion of U.S. citizens who consulted a provider of herbal medicine in a 1-year period increased from 10.2% in 1993 to 15.1% in 1998.² In addition, European countries spent almost \$5 billion (at manufacturers' prices to wholesalers) on over-the-counter herbal medicines in 2003. Germany and France are the indisputable leaders in over-the-counter sales (Fig. 74.1) and also have large markets for prescription herbal preparations.³ Complementary and alternative medicines including Chinese herbal medicines and herbal plants have been used by about 50% of Australians.¹

Herbal medicine use has been recorded in all of the ancient literature. To date, there are at least 11,000 species of plants for medicinal use, and about 500 of them are commonly used by various ethnic groups.^{1,4} These herbal plants may be used either in their primary forms or as mixtures. However, the source and composition of botanical medicines vary by prevalent local practices. Notably, these herbal remedies have not been tested for efficacy and safety, their ingredients are unknown, and the dosage and route of administration are not standardized. Although the prevalence of toxicity of organs caused by traditional medicines is directly related to a combination of ignorance, poverty, lack of medical facilities, lack of legislation, and widespread belief in indigenous systems of medicine in rural areas, it has been realized recently that the problems and concerns of herbal medicines arise from intrinsic toxicity, adulteration, contamination, substitution, misidentification, mistaken labeling, unfavorable herb-drug interactions, lack of standardization, or poor quality control.^{1,4} Increasing evidence for both adverse drug reactions and poisoning events associated with the use of herbal medicines has been reported worldwide. Adulteration of synthetic drugs and other potentially toxic compounds to herbal medicines has been identified. On the other hand, coadministration of herbal medicines with conventional drugs raises the potential of

herb-drug interactions, which may cause altered drug elimination, undertreatment, or toxicity.^{1,4,5}

HERBAL MEDICATIONS AND THE KIDNEY

Kidneys are particularly vulnerable to toxic injury because of their high blood flow rate, large endothelial surface area, high metabolic activity, active uptake by tubular cells, medullary interstitial concentration, and low urine pH. Renal tubules are involved in active transport and urinary concentration, and therefore the local concentration of toxins is potentially high, leading to direct injury to tubular cells. Herbal medicines may be toxic through one or more common pathogenic mechanisms. These include alteration of intraglomerular hemodynamics, tubular cell toxicity, inflammation, crystal nephropathy, rhabdomyolysis, and thrombotic microangiopathy. Compared with 30 years ago, patients today are usually taking multiple medications because of more underlying disease and have been exposed to more diagnostic and therapeutic procedures with the potential to harm kidney function. Thus, drug-related nephrotoxicity tends to be more common clinically. The patient-related risk factors for drug-induced nephrotoxicity include age older than 60 years, underlying renal insufficiency, glomerular filtration rate of less than 60 ml/min per 1.73 m², volume depletion, diabetes, heart failure, and sepsis.⁶ These risk factors may also make individuals susceptible to the renal toxicity of herbal medicines. An overview of the potential renal side effects of herbal medicines is shown in Figure 74.2. This chapter reviews current knowledge of the hazards related to herbal medicines for the kidneys.

Herbs That Lead to Kidney Injury

Tubulointerstitial Nephritis: Aristolochic Acid Nephropathy

Aristolochic acids (AAs) are a family of structurally related nitrophenanthrene carboxylic acids that are primarily derived from herbs of the genus *Aristolochia*, including *Aristolochia fangchi*, *Aristolochia clematitis*, and *Aristolochia manshuriensis* (Fig. 74.3). The predominant AAs are AAI (8-methoxy-6-nitro-phenanthro-(3,4-*d*)-1,3-dioxolo-5-carboxylic acid) and AAI (6-nitro-phenanthro-(3,4-*d*)-1,3-dioxolo-5-carboxylic acid). Long-term consumption of *A. fangchi* for slimming purposes was reported in Belgium. More than 100 young women suffered kidney damage, and several patients developed renal and urinary tract cancer (Fig. 74.4).⁷ Increasing evidence shows that AAs present in the herb are the compounds responsible for this renal toxicity.^{8,9} The nephrotoxic and carcinogenic effects of AAs in animals have been reported, and similar toxicities have been observed in

Figure 74.1 Distribution of the U.S. \$4.96 billion European market for over-the-counter herbal medicines in 2003. (From reference 3.)

Kidney Syndromes Induced by Herbal Medicines	
Hypertension	<ul style="list-style-type: none"> • <i>Glycyrrhiza</i> species (Chinese herbal teas, gancao, boui-ougi-tou) • <i>Ephedra</i> species (ma huang)
Acute tubular necrosis	<ul style="list-style-type: none"> • Traditional African medicine: toxic plants (<i>Securidaca longepedunculata</i>, <i>Euphoria matabelensis</i>, <i>Callilepis laureola</i>, Cape aloes, or adulteration by dichromate) • Chinese medicine: <i>Taxus celebica</i> • Morocco: Takaout roumia (paraphenylenediamine)
Acute interstitial nephritis	<ul style="list-style-type: none"> • Peruvian medicine (<i>Uno degatta</i>) • Tung Shueh pills (adulterated by mefenamic acid)
Fanconi syndrome	<ul style="list-style-type: none"> • Chinese herbs containing AAs (<i>Akebia</i> species, Boui, Mokutsu) • Chinese herbs adulterated by cadmium
Papillary necrosis	<ul style="list-style-type: none"> • Chinese herbs adulterated by phenylbutazone
Chronic interstitial renal fibrosis	<ul style="list-style-type: none"> • Chinese herbs or Kampo containing AAs (<i>Aristolochia</i> species, <i>Akebia</i> species, Mutong, Boui, Mokutsu)
Urinary retention	<ul style="list-style-type: none"> • <i>Datura</i> species, <i>Rhododendron molle</i> (atropine, scopolamine)
Kidney stones	<ul style="list-style-type: none"> • Ma huang (ephedrine) • Cranberry juice (oxalate)
Urinary tract carcinoma	<ul style="list-style-type: none"> • Chinese herbs containing AAs

Botanicals Known to Contain or Suspected of Containing Aristolochic Acid	
Botanical Name	Common or other names
<i>Aristolochia</i> spp.	Aristolochia, Guan Mu tong, Guang Mu tong
<i>Aristolochia acuminata</i> (Syn. <i>Aristolochia tagala</i>)	Oval leaf Dutchman's pipe
<i>Aristolochia bracteata</i>	Ukulwe
<i>Aristolochia clematidis</i>	Birthwort
<i>Aristolochia contorta</i>	Ma Dou Ling (fruit), Bei Ma Dou Ling (root), Tian Xian Teng (herb)
<i>Aristolochia cymbifera</i>	Mil homens
<i>Aristolochia debilis</i> (Syn. <i>Aristolochia Janga</i> , <i>A. recurvilabra</i> , <i>A. sinarum</i>)	Ma Dou Ling (fruit), Tian Xian Teng (herb), Qing Mu Xiang (root), Sei-Mokkou (Japanese), Birthwort, Long birthwort, Slender Dutchman's pipe
<i>Aristolochia fanachi</i>	Guang Fank ji (root), Fang ji, Fang chi, Makuboi (Japanese), Kou-boui (Japanese), Kwangbanggi (Korean)
<i>Aristolochia heterophylla</i>	Han Fang Ji
<i>Aristolochia indica</i>	Indian birthwort (root), Yin Du Ma Dou Ling
<i>Aristolochia kaempferi</i> (Syn. <i>Aristolochia chrysops</i> , <i>A. feddei</i> , <i>A. heterophylla</i> , <i>A. mollis</i> , <i>A. setchuenensis</i> , <i>A. shimadoi</i> , <i>A. thibetica</i> <i>isotrema chrysops</i> , <i>I heterophylla</i> , <i>I lasiops</i>)	Yellowmouth Dutchman's pipe, Zhu Sha Lian
<i>Aristolochia macrophylla</i> (Syn. <i>Aristolochia siphon</i>)	Dutchman's pipe
<i>Aristolochia manshuriensis</i> (Syn. <i>Hacquartia manchuriensis</i> , Syn. <i>Isotrema manchuriensis</i>)	Manchurian birthwort, Manchurian Dutchmans's pipe (stem), Guan Mutong (stem), Kan-Mokutsu (Japanese), Mokubai (Japanese), Kwangbanggi (Korean)
<i>Aristolochia maxima</i> (Syn. <i>Howardia hoffmanii</i>)	Maxima Dutchman's pipe, Da Ma Dou Ling
<i>Aristolochia mollissima</i>	Wooly Dutchman's pipe, Mian Mao Ma Dou Ling
<i>Aristolochia moupinensis</i>	Moupin Dutchman's pipe, Huai Tong
<i>Aristolochia serpentaria</i> (Syn. <i>Aristolochia serpentaria</i>)	Virginia snakeroot, Serpentaria, Virginia serpentina
<i>Aristolochia triangularis</i>	Triangular Dutchman's pipe, San Jiao Ma Dou Ling
<i>Aristolochia tuberosa</i>	Tuberous Dutchman's pipe, Kuai Jing Ma Dou Ling
<i>Aristolochia tubiflora</i>	Tubeflower, Dutchman's pipe, Guan Hua Ma Dou Ling
<i>Aristolochia versicolor</i>	Versicolour Dutchman's pipe, Bian Se Ma Dou Ling
<i>Asarum canadense</i> (Syn. <i>Asarum acuminatum</i> , <i>A. ambiguum</i> , <i>A. canadense</i> , <i>A. furcarum</i> , <i>A. medium</i> , <i>A. parvifolium</i> , <i>A. reflexum</i> , <i>A. rubracinctum</i>)	Wild ginger, Indian ginger, Canada snakeroot, False coltsfoot, Colic root, Heart snakeroot, Vermont snakeroot, Southern snakeroot, Jia Na Da Xi Xin
<i>Asarum himalaicum</i>	Tanyou-satshin (Japanese)
<i>Asarum splendens</i>	Do-satshin (Japanese)

humans. The renal syndrome was initially referred to as Chinese herb nephropathy (CHN) and later as AA nephropathy (AAN), a name more specific and mechanistic than CHN. AAN was soon recognized as a global health problem.^{7,8,10} Since the publication of the index cases, new cases of AAN have been reported, not only in Belgium but also worldwide (Fig. 74.4A). The true incidence of AAN is largely unknown and probably underestimated as numerous ingredients known to contain or suspected of containing AA are used in traditional medicine in China, Japan, and India (Fig. 74.5).¹¹

AAN is characterized by tubulointerstitial nephritis that rapidly progresses to fibrosis with deterioration of renal function, ultimately leading to end-stage renal failure in several months. The renal toxicity of AAI is dependent on the dosage and the duration of administration.¹² After multiple dosages or even a single dose, AAI is detectable in the kidneys for a long time. Human AAN is reproducible in rodents, in which AA intoxication results in tubular atrophy and interstitial fibrosis, leading to renal failure.¹³ The progressive tubular atrophy is related to impaired regeneration and apoptosis of proximal tubular epithelial cells, which is considered a possible mechanism of tubular epithelial cell deletion.

The resident fibroblast activation plays a critical role in the process of renal fibrosis during AA toxicity.¹⁴

Clinically, the initial presentation of AAN is usually silent and the renal failure is discovered by routine blood testing. However, a few cases reported in the literature have presented with Fanconi's syndrome or acute kidney injury due to acute tubular necrosis.¹⁵ Anemia is present and is often unusually severe in patients with severe renal impairment. In most of the cases, the urinary sediment is unremarkable, and dipstick analysis for albuminuria is negative. However, urinary excretion of low-molecular-weight proteins (e.g., β_2 -microglobulin, cystatin C) is markedly increased, and the urinary low-molecular-weight protein/albumin ratio is higher than in control patients with glomerular diseases.¹⁶

On pathologic examination, AAN is characterized by extensive renal interstitial fibrosis and tubular atrophy, which generally decreases in severity from the outer to the inner cortex (see Fig. 74.4C). The glomeruli are relatively spared, although, in the later stage of the disease, they also display a mild collapse of the capillaries and a wrinkling of the basement membrane.

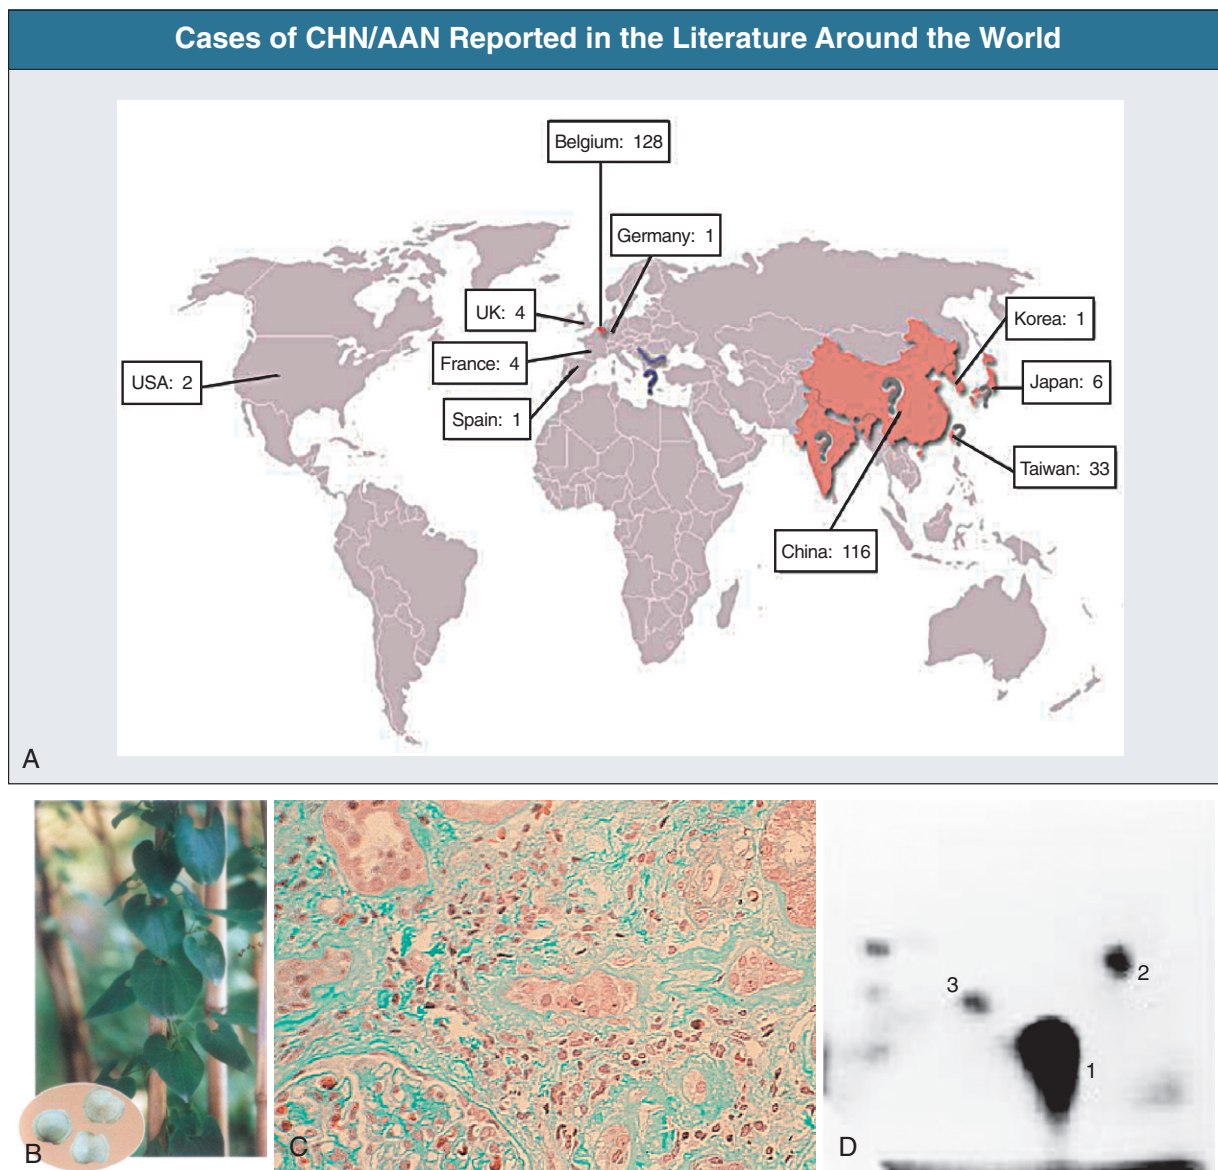

Figure 74.4 Chinese herb nephropathy/aristolochic acid nephropathy (CHN/AAN). **A**, Cases of CHN/AAN reported around the world. **B**, Guang Mu Tong, a Chinese herb which contains AAs. **C**, Extensive paucicellular interstitial fibrosis and tubular atrophy typically found in CHN/AAN. **D**, Auto-radiographic pattern of specific AA DNA adducts detected in human renal tissue. (Modified in part from reference 9.)

Figure 74.5 A pharmacy selling traditional herbal remedies (left) including fang chi and mu tong (right). The true incidence of AAN is largely unknown and probably underestimated as numerous ingredients known to contain or suspected of containing aristolochic acid are used in traditional medicine in India and eastern Asia. (From reference 9.)

Immune deposits are not found, but endothelial cell swelling is often apparent with consequent thickening of interlobular and afferent arterioles.^{11,17} An early and massive interstitial inflammation characterized by activated monocytes-macrophages and cytotoxic CD8⁺/CD103⁺ T lymphocytes has been demonstrated during the progression of experimental AAN,¹⁸ suggesting an immunologic process as a possible pathophysiologic mechanism.

The striking association between AA exposure and urothelial abnormalities was described for the first time by Cosyns and associates,¹⁹ who observed moderate atypia and atypical hyperplasia of the urothelium in four pieces of nephroureterectomies removed from three patients with AAN before or at the time of transplantation. The persistence of AA-DNA adducts in renal tissues of the cohort of Belgian women is consistent with the postulated role of AA in urothelial cancer. It accounts for 40%

to 45% of AAN patients who display multifocal high-grade transitional cell carcinomas, mainly in the upper urinary tract.⁹ Lemy and colleagues²⁰ reported a case series with 15-year follow-up and identified upper tract urothelial carcinoma as a potent risk factor for the subsequent development of bladder urothelial carcinoma after kidney transplantation for AAN. The molecular mechanism of AA-induced carcinogenesis shows a strong association between DNA adduct formation, mutation pattern, and tumor development. Analysis of DNA adducts formed in human target tissues (Fig. 74.4D) and studies in animal models have pointed out a major role of AAs in carcinogenesis. After oral ingestion of AA, extensive formation of AA-DNA adducts is observed in the forestomach, accompanied by development of tumors.¹ In 2002, the International Agency for Research on Cancer working group concluded that there is sufficient evidence in humans for the carcinogenicity of herbal remedies containing plant species of the genus *Aristolochia*.²¹

Studies have demonstrated that AA is a significant risk factor for Balkan endemic nephropathy,²² which is characterized by chronic interstitial fibrosis with slow progression to end-stage renal disease and urothelial malignant neoplasia (see Chapter 62). AA is proposed as one of the environmental causal factors for Balkan endemic nephropathy affecting thousands of people living in Bulgaria, Bosnia, Croatia, Romania, and Serbia along the Danube River basin.²³

There is no proven treatment of AAN. A pilot study with corticosteroids was performed in 35 AAN patients with chronic renal failure. Compared with an untreated group, there was a significant reduction of the number of patients reaching end-stage renal disease observed after 1 year of corticosteroid therapy.²⁴ Eight years later, in a larger group of AAN patients, the corticosteroid therapy was confirmed to slow the progression of renal failure.²⁵ As patients with AAN seem to be at an increased risk for uroepithelial malignant neoplasms, such patients should at least be regularly screened by urine cytologic examinations. Some authors recommend prophylactic removal of the native kidneys and ureters in all patients with end-stage AAN who are being treated with either transplantation or dialysis.²⁶

Acute Kidney Injury

The nephrotoxicity of medicinal herbs most frequently reported in the literature is from countries in southern Africa and Asia. The use of traditional herbal remedies has been implicated in 37.5% of all cases of acute kidney injury in Nigeria.²⁷ Herbal plants reported as the cause of renal damage include *Securidaca longepedunculata* (or violet tree), which contains methylsalicylate and saponin; *Euphorbia matabelensis*, which contains latex; *Crotalaria laburnifolia*, which contains hepatonephrotoxic alkaloids; *Uncaria tomentosa* (cat's claw); *Lepidium meyenii* (common name: maca); *Tripterygium wilfordii* (lei gong teng); licorice (*Glycyrrhiza glabra*) root; and *Callilepis laureola* (impila). This section describes some of the important examples of nephrotoxicity caused by herbal remedies.

Tripterygium wilfordii Hook F (TWHF) is a kind of Chinese herbal medicine used for 2000 years. It was applied externally for treatment of arthritis and inflammatory tissue swelling for many years. This drug has been found to have immunosuppressive effects that could successfully induce remission of some autoimmune disorders. Its side-effects include gastrointestinal upset, infertility, and suppression of lymphocyte proliferation. A case was reported of a previously healthy young man who developed profuse vomiting and diarrhea, leukopenia, renal failure, profound hypotension, and shock after ingestion of an

extract of TWHF. In addition to his hypovolemic shock, he had evidence of cardiac injury by electrocardiography, cardiac enzyme studies, and echocardiography. He died of intractable shock 3 days after the abuse of TWHF. In rats, daily intragastric ingestion of an effective compound extracted from *T. wilfordii* Hook F for 16 days led to dysfunction of the proximal tubule of the kidney.²⁸

Cat's claw, or *uno de gato*, is a Peruvian herbal preparation made from *Uncaria*, a woody vine found in the Amazon basin. It has been used for various diseases, such as cirrhosis, gastritis, gonorrhea, cancers of the female genital tract, and rheumatism. The oxindole alkaloids from the root bark of cat's claw are thought to invoke its most widely sought-after medicinal effects as an herbal remedy against inflammation. However, it appears that additional unknown substances have an important role in the overall effect of cat's claw extracts. A case of acute interstitial nephritis after the use of this preparation has been reported; renal biopsy showed acute interstitial nephritis, and the renal failure was reversed after withdrawal of the agent. The acute interstitial nephritis is likely to be an idiosyncratic allergic reaction to the remedy.²⁹

A variety of nephrotoxic mushrooms are confused with edible mushrooms, resulting in acute kidney injury throughout Europe and North America. The *Cortinarius* species (*Cortinarius callisteus*, *Cortinarius cinnamomeus* group, *Cortinarius gentilis*, *Cortinarius orellanus*, *Cortinarius rainierensis*, *Cortinarius speciosissimus*, *Cortinarius splendens*, and *Cortinarius semisanguineus* group) are the most notorious. In North America, the most common mushroom is probably *C. gentilis*. In 2004, mushroom exposures accounted for 8601 cases and five fatalities, but only three exposures were attributed to the *Cortinarius* group.³⁰ However, because more than 80% of mushroom exposures fell into the unknown mushroom category, *Cortinarius* exposures certainly are higher.³⁰ Clinically, the history of mushroom ingestion may be remote, particularly with *Cortinarius*. Although early gastrointestinal symptoms are usually noted at the time of intake, they may not be severe enough for patients to seek medical attention, and symptoms of renal failure may not be manifested until 1 to 3 weeks after exposure. Presentation with a shorter latent period suggests a more severe toxicity and greater risk of severe renal failure than with delayed presentation. Improvement in renal injury may occur within several weeks to months; however, renal injury may last months to years, and patients may require chronic hemodialysis or renal transplantation.

A more recently described mushroom syndrome involves *Amanita smithiana/proxima*. It is thought that the toxin is 2-amino-4,5-hexadienoic acid.³¹ Although it causes acute tubular necrosis within hours of ingestion, the clinical outcome is usually good.

Herbal Remedies and Renal Complications

Hypertension

Ma huang, an ephedra-containing herbal preparation, is used in the treatment of bronchial asthma, cold and influenza symptoms, fever and chills, headaches and other aches, edema, and lack of perspiration. In Western countries, ephedrine and herbal ephedra preparations have been used to promote weight loss and to enhance athletic performance. Dietary supplements that contain ephedra alkaloids have been reported to possibly induce hypertension, palpitations, tachycardia, and stroke. A report showed that prescribed ephedrine is not associated with a substantially increased risk of adverse cardiovascular outcomes in a

registry-based case-crossover study.³² However, ephedra may pose a serious health risk to some users, such as renal patients who are particularly prone to hypertension.

The dried roots of the licorice plant (*Glycyrrhiza glabra*) have been consumed for the past 6000 years and are used as flavoring and sweating agents, as demulcents and expectorants in the Western world, and as antiallergic and anti-inflammatory agents in Asian countries, including China, Japan, and Korea. Licorice contains glycyrrhizin. After oral administration of licorice preparations, glycyrrhizinic acid is hydrolyzed by intestinal bacteria into glycyrrhetic acid. Glycyrrhetic acid can inhibit the enzyme 11 β -hydroxysteroid dehydrogenase 2, which in the distal kidney tubules converts the steroid hormone cortisol to cortisone. A decreased activity of 11 β -hydroxysteroid dehydrogenase 2 leads to an excess of cortisol and an overstimulation of this mineralocorticoid receptor, leading to water and sodium retention and an increased excretion of potassium. With exposure to large doses of glycyrrhizinic acid for a prolonged period, it can cause hypokalemia, hypernatremia, arrhythmia, edema, pseudoaldosteronism, hypertension, and cardiac disorders.¹ To minimize the adverse effects, it is recommended that licorice not be ingested for longer than 4 to 6 weeks.³³

Crystalluria and Nephrocalcinosis

Many health drinks that are well tolerated by individuals with normal renal function can cause serious problems in patients with limited renal function. One example of this is oxalate crystalluria. Star fruit carambola juice can contain as much as 800 mg of oxalate in 4 ounces (120 ml). Sour carambola juice is a popular beverage in Taiwan, and although commercial carambola juice prepared by pickling and dilution has markedly reduced oxalate content, fresh juice or only mildly diluted post-pickled juice may contain high quantities of oxalate. Cranberry concentrate tablets also can lead to an increase in urinary excretion of oxalate. Ma huang ingestion also has been reported to lead to kidney stones, and the use of ephedrine and guaifenesin individually or in combination has been shown to cause more than 35% of urinary stones that are related to pharmaceutical metabolites and 0.1% of all urinary stones.³⁴

Hyperkalemia

One of the most common recommendations made for people with renal impairment is tight control of potassium intake. This is especially true in light of the side effects with regard to increased potassium for many of the medications we prescribe to slow the progression of renal disease. The normal food sources for increased intake are oranges, bananas, tomatoes, and potatoes. However, some health drinks are also very high in potassium. Noni juice is often taken to increase energy, but it contains more potassium than any other fruit juice. The legume alfalfa (*Medicago sativa*) and the plants dandelion (*Taraxacum officinale*), stinging nettle (*Urtica dioica*), and horsetail (*Equisetum arvense*) all contain significant amounts of potassium as well³⁵ and may induce hyperkalemia, especially in patients with chronic kidney injury.

Urinary Obstruction

Djenkol beans or jering (*Pithecellobium jeringa*) are broad, round, reddish beans that grow during monsoon season in Myanmar, Indonesia, and Malaysia and are considered a delicacy. The jering seeds are extolled for their supposed ability to prevent diabetes and high blood pressure. In addition, the seeds do have bladder spasmodic properties and are also used as a remedy to

eliminate stones from the bladder. The jering poisoning or djenkolism is characterized by spasmodic pain, urinary obstruction, and acute kidney injury.³⁶ The underlying pathologic process is an obstructive uropathy. On a more chronic basis, djenkol bean consumption is associated with a fourfold higher risk of nonglomerular hematuria.³⁷

Renal Toxicity from Contaminants in Herbal Medicines

Herbal medicines may be contaminated with excessive or banned pesticides, microbial contaminants, heavy metals, and chemical toxins or adulterated with orthodox drugs. These contaminants are related to the source of these herbal materials, if they are grown in a contaminated environment, or to collection of the plant materials. The herbal materials may be contaminated with chemical toxins unintentionally or intentionally during the storage of the herbs. The presence of orthodox drugs is often due to the intentional alteration of the herbal remedy by the manufacturers.³⁸ A federal government report found undeclared pharmaceuticals or heavy metals in 32% of Asian medicines sold in the state of California. These include ephedrine, chlorpheniramine, methyltestosterone and phenacetin, sildenafil, steroids, and fenfluramine; 10% to 15% have lead, mercury, or arsenic. Of more than 500 Chinese drugs, approximately 10% contain undeclared drugs or heavy metals.⁴

A number of case reports have demonstrated adulterations leading to renal injury. One described a 73-year-old Malaysian woman who presented with renal failure and bilateral papillary necrosis. She had osteoarthritis and had been consuming two tablets of a traditional herbal preparation, freely available from Chinese medical halls, daily for the past 10 years. She denied the consumption of other analgesics. The product inserts of these preparations stipulated that their only active ingredients were Chinese herbs. However, analysis of the herbal preparation demonstrated the presence of 120 mg of phenylbutazone per tablet. The second report described a 34-year-old housewife who had been taking a mixture of Chinese herbs to strengthen her health. She presented with Fanconi's syndrome and a nephrogenic diabetes insipidus and was found to have a urinary excretion of cadmium 50 times greater than normal. Another report described a patient who presented with a rapid onset of dialysis-requiring acute kidney injury, with marked albuminuria, microscopic pyuria, and hematuria after a 4-week treatment with Tung Shueh pills for arthralgias. A renal biopsy demonstrated acute interstitial nephritis with an inflammatory infiltrate consisting of lymphocytes and eosinophils. The Tung Shueh pills were analyzed and found to contain both diazepam and mefenamic acid as additives. In Morocco, the traditional el badia, a powder made of the seeds of *Tamarix orientalis*, is used by women for hair dye; however, when the *T. orientalis* seeds are scarce, they are replaced with roumia, which contains paraphenylenediamine. This substitution is responsible for about 10% of all cases of acute kidney injury, 50% of all cases of rhabdomyolysis, 25% of intensive care unit admissions for poisonings, and two thirds of poisoning-related deaths in Morocco.^{4,6}

In Thailand and other parts of Southeast Asia and India, herbal remedies have been shown to be contaminated with lead, cadmium, and mercury. In South Africa, about 15% of herbs have been found to be contaminated with uranium. In the United States, ginseng dietary supplements have been shown to contain the pesticides quintozene and hexachlorobenzene or to have exceeded the standard for lead content.

Herb-Drug Interactions Resulting in Adverse Renal Effects

Herbs are often administered in combination with therapeutic drugs, raising the potential of pharmacokinetic or pharmacodynamic herb-drug interactions. A number of herb-drug interactions have been noted to alter efficacy and adverse events. Pharmacokinetic herb-drug interactions are due to altered absorption, metabolism, distribution, and excretion of drugs. Frequently, one of the underlying mechanisms of altered drug concentrations by concomitant herbal medicines is the induction or inhibition of hepatic and intestinal cytochrome P-450. By searching the literature, it has been found that a total of 32 drugs interact with herbal medicines in humans. These drugs mainly include anticoagulants (warfarin, aspirin, and phenprocoumon), sedatives and antidepressants (midazolam, alprazolam, and amitriptyline), oral contraceptives, anti-HIV agents (indinavir, ritonavir, and saquinavir), cardiovascular drugs (digoxin), immunosuppressants (cyclosporine and tacrolimus), and anticancer drugs (imatinib and irinotecan). Most of them are substrates for cytochromes or P-glycoprotein, and many have narrow therapeutic indices. Toxicity arising from drug-herb interactions may be minor, moderate, or even fatal, depending on a number of factors associated with the patients, herbs, and drugs.¹

St. John's wort, derived from the plant *Hypericum perforatum*, has been used since ancient times for depression and anxiety. It is the most common antidepressant used in Germany. St. John's wort induces a hepatic enzyme through activation of the cytochrome P-450 system. Through these mechanisms, St. John's wort can decrease plasma levels of a wide range of prescribed drugs, with possible serious clinical consequences. For example, St. John's wort ingested for 10 days by a group of healthy volunteers reduced the bioavailability of digoxin by an average of 25%. St. John's wort ingested for 2 weeks reduced total absorption of indinavir by 50%, which is large enough to cause treatment failure. Case reports indicated significant increases in the metabolism of other drugs, including warfarin, theophylline, oral contraceptives, and cyclosporine. In transplant recipients, toxicity and underdosage of calcineurin inhibitor-based immunosuppression have been linked to phytochemically triggered activity changes of cytochrome P-450 isoenzyme CYP3A4 metabolism and drug transport proteins. Concomitant use of St. John's wort in renal transplant recipients treated with cyclosporine or tacrolimus could favor graft rejection.^{39,40}

Ginkgo biloba, one of the most popular plant extracts in Europe, recently received approval in Germany for treatment of dementia. *G. biloba* is composed of several flavonoids, terpenoids (e.g., ginkgolides), and organic acids believed to act synergistically as free radical scavengers. It has been suggested that *G. biloba* should not be administered with concomitant anticoagulation or in patients with bleeding disorders. Hence, concomitant use of aspirin or any of the nonsteroidal anti-inflammatory drugs (NSAIDs), as well as of anticoagulants such as warfarin and heparin, is ill-advised. Spontaneous hyphema and spontaneous bilateral subdural hematomas have been observed in patients taking *G. biloba* and attributed to ginkgolide B, a potent inhibitor of platelet-activating factor needed to induce arachidonate-independent platelet aggregation. Hemorrhagic complications were observed often in patients administered concomitant antiaggregant or anticoagulant therapy. The exact mechanism of the interaction of *G. biloba* with aspirin, warfarin, and NSAIDs remains unclear. Experimental data from rats suggest that a *G. biloba* diet markedly increased the content of cytochrome P-450

and activity of glutathione S-transferase and markedly induced the level of CYP2B1/2, CYP3A1, and CYP3A2 messenger RNA in the liver.⁴¹

In summary, herbal medicines may exert renal toxicity through their inherent properties, occasionally dose-related or idiosyncratic toxicity, herb-drug interactions, and misidentification and adulteration of the preparation. Various renal syndromes have been reported after the use of herbal medicines. They include acute tubular necrosis, acute interstitial nephritis, Fanconi's syndrome, hypokalemia, hypertension, papillary necrosis, chronic interstitial nephritis, nephrolithiasis, urinary retention, and cancer of the urinary tract. Conversely, herbal medicine may also be hazardous for renal patients because it may interact with such drugs as cyclosporine or carry significant amounts of potassium. Until now, most published data about the toxicity of herbal medicines are case reports. Precise identities of the culprit substances, the toxicologic characteristics, and the pathogenic mechanisms in herbal medicines remain largely unknown. Whereas many herbs have been used for centuries without incidence of acute kidney injury, insidious damage caused by long-term use is a concern because many herbs have not been rigorously tested for toxicity. Some Web sites provide data on herbal therapy hazards (Fig. 74.6),⁶ which may be helpful for nephrologists to obtain specific information about specific herbs that their patients may use.

OVER-THE-COUNTER MEDICINES AND THE KIDNEY: ANALGESIC NEPHROPATHY

In recent years, we have witnessed the increasing popularity of over-the-counter (OTC) health foods, nutraceuticals, and medicinal products from plants or other natural sources in the developed countries. However, OTC analgesics are one of the most widely used classes of drugs in the United States. The primary indications for use of OTC analgesics include fever and minor aches and pains. NSAIDs, such as aspirin, ibuprofen, and naproxen sodium, are also used to treat inflammatory conditions, and aspirin is used prophylactically as an anticoagulant in thrombosis-related disorders. Acetaminophen, aspirin, ibuprofen, and naproxen sodium are available over the counter. Population studies and World Health Organization statistics indicate that 10% to 50% of individuals have a history of musculoskeletal disorders. Easy access to some of these OTC analgesics and combinations by the general public runs the risk of unwarranted and unsupervised chronic intake. Although studies on the association between the long-term use of aspirin, NSAIDs, and other analgesics and end-stage renal disease have given conflicting results, many studies have suggested an association between chronic ingestion of analgesics and kidney disease. A retrospective cohort study using data from the Australia and New Zealand Dialysis and Transplant registry showed that of 31,654 patients with incident renal replacement therapy, 10.2% had analgesic nephropathy. Patients with analgesic nephropathy have more comorbidities and poorer survival on renal replacement therapy, especially among younger patients.⁴² Because of the widespread use of analgesics, even a small increased risk of kidney disease will have major public health implications.

A National Kidney Foundation position paper defines analgesic nephropathy as a disease resulting from the habitual consumption during several years of a mixture containing at least two antipyretic analgesics and usually codeine or caffeine. It is characterized by kidney papillary necrosis and chronic interstitial

nephritis that leads to insidious onset of progressive kidney failure. NSAIDs, such as aspirin, ibuprofen, and naproxen sodium, inhibit cyclooxygenase and may inhibit lipoxygenase, decreasing the production of prostaglandins and leukotrienes, which accounts for many NSAID-induced renal effects. In patients with volume depletion, renal perfusion depends on circulating prostaglandins to vasodilate the afferent arterioles, allowing more blood flow through the glomerulus. The contribution of prostaglandins to renal homeostasis is most critical in elderly patients and those with circulatory disturbances, such as renal or liver dysfunction, congestive heart failure, or volume depletion.⁴³

The early-phase changes of analgesic nephropathy in humans were first demonstrated in patients with normal kidney function with a history of phenacetin and acetylsalicylic acid consumption (ingestion of a minimum of five tablets a day for 5 years). Histologic lesions seen in experimentally induced analgesic nephropathy are similar to those seen in humans. Medullary ischemia seems to be the initiating event. Light microscopy and electron microscopy reveal irreversible damage to medullary interstitium, characterized by interstitial cell nuclear degeneration, abnormal interstitial matrix, loss of medullary interstitial cells, and increased collagen. The earliest changes involve sclerosis of vasa recta capillaries and patchy tubular necrosis. Later changes include

areas of papillary necrosis and secondary focal segmental glomerulosclerosis, cortical scarring, and interstitial fibrosis. Papillary necrosis may also be the result of reactive metabolic products of the drug or the accumulation of phospholipids in the papilla.

The clinical symptoms of analgesic nephropathy include polyuria, sterile leukocyturia, and microscopic hematuria. Progression is insidious, and clinical findings in later stages are related to advanced renal failure. Diagnosis can be made by ultrasound or intravenous urography (see Fig. 50.4C), but a computed tomography (CT) scan finding of irregular kidneys with papillary necrosis and calcification is the most sensitive and specific method of diagnosis of analgesic nephropathy (Fig. 74.7).⁴⁴ A staging system for analgesic nephropathy based on CT scan appearances has been proposed by Elseviers and coworkers.⁴⁴

It is important to highlight the potential adverse effects of analgesic agents on the kidney. Patients who warrant chronic therapy with these agents should be closely monitored for any early signs of kidney injury. Early detection and removal of the offending agent could halt or even reverse analgesic-induced kidney injury. There is a pressing need for multicenter trials to assess the true incidence of this problem and to study the effects of various analgesic agents (alone and in combination) in at-risk populations. Analgesic nephropathy is also discussed in Chapter 62.

Epidemiology and Pathophysiology of Chronic Kidney Disease

Aminu Bello, Bisher Kawar, Mohsen El Kossi, Meguid El Nahas

DEFINITION

Chronic kidney disease (CKD) is defined as kidney damage or glomerular filtration rate (GFR) below 60 ml/min per 1.73 m² for 3 months or more irrespective of the cause. The Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines have classified CKD into five stages.¹ This classification, although useful in simplifying the categorization of CKD, has its limitations, which include classifying people with isolated microalbuminuria as suffering from CKD, labeling mild and stable kidney damage as CKD, and not differentiating between age-related impaired kidney function and progressive disease-induced CKD.²

In 2005, the Kidney Disease: Improving Global Outcomes (KDIGO) group suggested clarifications including the addition of the suffix T for patients with renal allografts and D to identify CKD stage 5 patients on dialysis.³

The U.K. National Institute of Health and Clinical Excellence (NICE) has modified, in 2008, the KDOQI CKD classification by subdividing CKD stage 3 into 3A and 3B, estimated GFR of 45 to 59 ml/min per 1.73 m² and 30 to 44 ml/min per 1.73 m², respectively.⁴ The NICE CKD guidelines also stipulated that the suffix *p* be added to the stages in proteinuric patients (Fig. 75.1). This refinement of the initial CKD classification by NICE assumes that there is a distinction between patients with GFR below 60 ml/min per 1.73 m² and those with GFR below 45 ml/min per 1.73 m² in terms of prognosis and that the presence of significant proteinuria has to be acknowledged in the classification.⁴

EPIDEMIOLOGY OF CHRONIC KIDNEY DISEASE

The true incidence and prevalence of CKD within a community are difficult to ascertain as early to moderate CKD is usually asymptomatic. However, various epidemiologic studies attempted to clarify that issue and have made relatively similar observations suggesting a prevalence of CKD of around 10%, albuminuria (mostly microalbuminuria) of around 7%, and GFR below 60 ml/min per 1.73 m² of around 3% (Fig. 75.2).

Of note, most of these studies are limited by the fact that individuals were tested only once, thus precluding a clear assumption of chronicity. The high prevalence of CKD is confounded by a number of facts:

1. Microalbuminuria is considered a marker of CKD when it may merely reflect underlying vascular disease, endothelial dysfunction, or atherosclerosis or chronic inflammatory conditions such as hepatitis, dermatitis, and colitis. Also, microalbuminuria is associated with aging, obesity, and smoking. Finally, it is often transient and reversible.

2. The majority of those screened within the community and found to have reduced GFR are elderly individuals. Age is known to be associated with a decline in kidney function that some consider physiologic, whereas others attribute it to underlying vascular aging and pathologic processes, mostly atherosclerosis and progressive renal ischemia.
3. Formulae such as the Modification of Diet in Renal Disease (MDRD) and Cockcroft-Gault are used to estimate GFR in spite of their known limitations and underestimation of normal kidney function (bias and imprecision) (see Chapter 3).

All these limitations of current CKD screening strategies may tend to overinflate the overall prevalence of significant CKD.

EPIDEMIOLOGY OF END-STAGE RENAL DISEASE

Incidence of end-stage renal disease (ESRD) refers to the number of patients with ESRD beginning renal replacement therapy (RRT) during a given time (usually a year) in relation to the general population; it is usually expressed as number of patients per million population per year. Of note, the incidence of ESRD according to most national registries does not take into account patients not treated by RRT; therefore, it underestimates the overall true incidence of ESRD (CKD stage 5).

The prevalence of ESRD is the proportion in a specific population who have ESRD at a given time; it encompasses both new and continuing patients on RRT; it is expressed as patients per million population. Prevalence is a function of the incidence (new cases) and outcomes (transplantation or death) rates of ESRD in a given population.

The global epidemiology of ESRD is heterogeneous and influenced by several factors. Consequently, the incidence and prevalence of ESRD vary widely from country to country (Fig. 75.3).

Disparities in the incidence and prevalence of ESRD within and between developed countries reflect racial and ethnic diversities as well as their impact on the prevalence of diabetes and hypertension in respective countries and communities. Recently, different progression rates of CKD in the population, referral patterns, and quality of pre-ESRD care have been linked to the heterogeneity of ESRD rates in different parts of the world. Disparities with developing countries are likely to reflect availability of and access to RRT in low and middle economies.

The cost of treating patients with ESRD is substantial and has an impact on provision of care. In this context, it has been proposed that there is a clear and direct relationship between nations' gross national product and the availability of RRT in most countries.⁵ It was pointed out that during the next decade,

even the industrialized nations will struggle to meet the demands of expanding ESRD programs; in the United States, it has been estimated that the annual expenditure on ESRD will reach more than U.S. \$52 billion by 2030.⁶ In the United Kingdom, renal services currently consume about 2% of the National Health Service budget, and this is set to rise with increasing numbers of individuals requiring RRT.⁷ Globally, it has been estimated that by 2010, more than 2 million individuals will be treated by RRT at a cost of \$1 trillion during the decade.⁸ The great majority (90%) of those treated live in high economies. More than 100 of 212 countries worldwide with low and middle economies do not have any provision for RRT.⁹ Consequently, in many low and middle economy countries, ESRD is a death sentence.

Classification of CKD Based on GFR	
CKD Stage	Definition
1	Normal or increased GFR; some evidence of kidney damage reflected by microalbuminuria, proteinuria, and hematuria as well as radiologic or histologic changes
2	Mild decrease in GFR (89–60 ml/min per 1.73 m ²) with some evidence of kidney damage reflected by microalbuminuria, proteinuria and hematuria as well as radiologic or histologic changes
3 3A 3B	GFR 59–30 ml/min per 1.73 m ² GFR 59 to 45 ml/min per 1.73 m ² GFR 44 to 30 ml/min per 1.73 m ²
4	GFR 29–15 ml/min per 1.73 m ²
5	GFR <15 ml/min per 1.73 m ² ; when renal replacement therapy in the form of dialysis or transplantation has to be considered to sustain life
The suffix p to be added to the stage in proteinuric patients (proteinuria >0.5 g/24h)	

Figure 75.1 Classification of CKD based on GFR as proposed by the Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines and modified by NICE in 2008. (From references 1 and 4.)

SCREENING FOR CHRONIC KIDNEY DISEASE

Current Screening Guidelines

In view of the rising number of those suffering from ESRD and the perceived high prevalence of CKD in communities, interest has focused on the early detection of CKD and those at risk. Several guidelines for screening, mostly targeted to high-risk individuals, have been issued and implemented worldwide. Those include the U.S. KDOQI, the U.K. CKD NICE, and the Australian Caring for Australasians with Renal Impairment (CARI) guidelines, to name a few.^{1,4,10} There are few differences as to the recommended targeted populations, but they invariably include individuals with hypertension and diabetes mellitus. Other groups include those with a family history of CKD; obese individuals; those with cardiovascular diseases, especially congestive heart failure; people with multisystem diseases; ethnic groups with high prevalence of CKD; and those with urologic conditions, such as nephrolithiasis. The KDOQI guidelines additionally recommend screening those older than 65 years. Screening should consist of a urine albumin/protein estimation as well as measurement of serum creatinine and estimation of GFR (see Chapter 3). General population CKD screening is unlikely to be realistic or cost-effective. Targeted screening is the most cost-effective approach (Fig. 75.4).

Overall, CKD screening would best be associated with broader national strategies and programs to minimize cardiovascular disease (CVD). This is the essence of the U.K. national vascular campaign/strategy launched in 2009 and aiming to screen those older than 40 years for CVD risk, including, when appropriate, CKD. Similar strategies have been initiated by the Centers for Disease Control and Prevention in the United States and in Australia.

NATURAL HISTORY OF CHRONIC KIDNEY DISEASE

The natural history of CKD stages 1 and 2 remains to be fully defined. It has generally been assumed that the majority of patients with CKD stages 3B to 5 progress relentlessly to ESRD.

Figure 75.4 International recommendations for targeted screening for CKD. KDOQI, Kidney Disease Outcomes Quality Initiative; U.K. NICE, U.K. National Institute of Health and Clinical Excellence; CARI, Australian Caring for Australasians with Renal Impairment; CSN, Canadian Society of Nephrology.

This has recently been challenged as progression is variable, and a sizable percentage of these patients have stable kidney function or die prematurely of CVD.¹¹ A Canadian study showed the natural history of CKD stages 3 and 4 to be variable and reflecting the patient's risk factor profile.¹² Many CKD patients with GFR below 60 ml/min per 1.73 m² die from cardiovascular or other causes before reaching ESRD.

A straight-line relationship is often found between the reciprocal of serum creatinine (1/S_{Cr}) values or the estimated GFR and time (for methodologic aspects, refer to Chapter 76). However, a significant percentage of patients do not progress in a predictable linear fashion and have breakpoints in their progression slopes, suggesting acceleration or slowing down of the rate of progression of CKD. These breakpoints could be either spontaneous or secondary to events such as infections, dehydration, changes in the adequacy of systemic blood pressure control, and exposure to nephrotoxins, in particular nonsteroidal anti-inflammatory drugs (NSAIDs) or radiocontrast agents. Attention has also been drawn recently to the impact of intercurrent acute kidney injury (AKI) events on the rate of progression of CKD. It is also important to appreciate that some patients with mild to moderate CKD have stable renal function for sustained periods.^{11,12}

The rate of progression of CKD also varies according to the underlying nephropathy and between individual patients. Historically, the rate of decline in GFR of patients with diabetic nephropathy has been among the fastest, averaging around –10 ml/min per year. Control of systemic hypertension slows the rate of GFR decline to –5 ml/min per year, with further improvement (–1 to –2 ml/min per year) expected in patients whose glycemia and hypertension are optimally controlled and in those treated with inhibitors of the renin-angiotensin-aldosterone system (RAS). In nondiabetic nephropathy, the rate of progression of CKD was 2.5 times faster in patients with chronic glomerulonephritis than in those with chronic interstitial nephritis and 1.5 times faster than in those with hypertensive nephrosclerosis. The association of proteinuria and faster progression of CKD was highlighted in a number of studies (reviewed in reference 13). Relief of obstruction, discontinuation of nephrotoxic agents, and control of hypertension often stabilize renal function in a large percentage of patients. Patients with polycystic kidney disease and impaired renal function, CKD stage 3B and beyond, may also have a faster rate of progression compared with other nephropathies. The rate of progression of CKD in the elderly has been associated with incident and progressive underlying cardiovascular disease. This is of interest as an increasing number of elderly patients reach ESRD, and renovascular disease has become one of the most common causes of ESRD in some countries.¹⁴

FACTORS AFFECTING INITIATION AND PROGRESSION OF CHRONIC KIDNEY DISEASE

CKD is likely to be a multi-hit process. Risk factors for CKD include susceptibility, initiation, and progression factors. Susceptibility factors predispose to CKD, whereas initiation factors directly trigger kidney damage. Progression factors are associated with worsening of already established kidney damage. The aim of identifying susceptibility and initiation factors for CKD is to define individuals at high risk for development of CKD; with progression factors, the aim is to define individuals at high risk for worsening (CKD) kidney damage and subsequent loss of kidney function (Fig. 75.5).

Summary of Risk Factors Associated with the Initiation and Progression of CKD	
Initiation Factors	Progression Factors
Systemic hypertension	Older age
Diabetes mellitus	Gender (male)
Cardiovascular disease	Race/ethnicity
Dyslipidemia	Genetic predisposition
Obesity/metabolic syndrome	Poor blood pressure control
Hyperuricemia	Poor glycemia control
Smoking	Proteinuria
Low socioeconomic status	Cardiovascular disease
Nephrotoxins exposure: NSAIDs, analgesics, traditional herbal use, heavy metals exposure (such as lead)	Dyslipidemia Smoking Obesity/metabolic syndrome Hyperuricemia Low socioeconomic status Alcohol consumption Nephrotoxins; NSAIDs, RCM, herbal remedies Acute kidney injury

Figure 75.5 Summary of risk factors associated with the initiation and progression of CKD. NSAIDs, nonsteroidal anti-inflammatory drugs; RCM, radiocontrast material.

These risk factors are further classified according to feasibility for intervention as modifiable and nonmodifiable (see Fig. 75.5). The classification can also be clinical (diabetes, hypertension, autoimmune diseases, systemic infections, drugs, or toxins) and sociodemographic (age, race, poverty/low income). A number of these risk factors have been identified in longitudinal community-based studies (see Fig. 75.5).

Known CKD susceptibility factors include genetic and familial predisposition, race (Afro-Caribbeans, Indo-Asians), maternal-fetal factors (low birth weight, malnutrition *in utero*), age (elderly), and gender (male) (reviewed in references 1 and 15). Beyond the susceptibility to CKD, additional initiation factors are likely to trigger disease. These are listed in Figure 75.5.

CHRONIC KIDNEY DISEASE PROGRESSION FACTORS

Once it is established, CKD (eGFR <60 ml/min) progression is influenced by a number of modifiable and nonmodifiable risk factors.¹⁶

Nonmodifiable Progression Risk Factors

Age

The rate of progression of CKD is influenced by age; elderly patients affected by glomerulonephritis seemingly have a faster rate of GFR decline. However, longitudinal studies of subjects without CKD have observed a decline in GFR with increasing age in some subjects, implying that nephron loss may be part of normal aging. This is corroborated by recently published longitudinal data from Norway.¹⁷ However, in one such study, the Baltimore Longitudinal Study, more than a third of individuals did not have a decline in kidney function with aging.

Age-related progression may be affected by underlying CVD and atherosclerosis.¹⁸

Gender

This is an important demographic factor associated with development and progression of CKD. It has been reported that ESRD due to all causes occurs more frequently in men than in women. According to the USRDS Annual Data Report,⁶ there is preponderance in the prevalence of all-cause ESRD in favor of men, but this has not been reported to be so marked in Europe. In most CKD studies and meta-analyses, women have a slower rate of progression compared with men.⁶

Race

In the United States, for all causes of ESRD, African Americans have a faster rate of progression than their Caucasian cohorts do. The incidence and prevalence of diabetic and hypertensive CKD are higher in African and Hispanic Americans compared with Caucasians.¹⁹ Their rate of CKD progression also seems faster, although few studies confirmed this by multivariate analysis. The mechanisms underlying these associations remain to be elucidated, but possible explanations include racial and genetic factors, lower nephron endowment, and increased susceptibility to salt-sensitive hypertension as well as environmental, lifestyle, and socioeconomic differences. The last may have an impact on access to health care and compliance with treatment.

Genetics

Studies have demonstrated that genetic factors play a crucial role in CKD and ESRD, mostly through linkage and association analyses with candidate gene approaches. Recent technologic advancements in genome-wide association studies are likely to uncover new CKD susceptibility genes.

Associations have been described between certain major histocompatibility complex loci and the rate of CKD progression. Patients with polycystic kidney disease carrying the genotype *PKD1* are thought to have a worse prognosis than others. Progression of CKD may also be influenced by polymorphisms of genes coding for putative mediators of renal scarring, including those coding for the renin-angiotensin-aldosterone system (RAAS) (reviewed in reference 20). The human homologue of the rat renal failure (*Rf*) gene has been localized to the long arm of chromosome 10. In African Americans with ESRD due to a variety of nephropathies, an association between two markers (D10S1435 and D10S249) spanning 21 polymorphic regions of chromosome 10 approached significance in nondiabetic patients. It was also reported that genetic variation at the *MYH9* locus or sequence variants in the *APOL1* gene could explain the increased burden of focal segmental glomerulosclerosis and hypertensive ESRD among African Americans (see Chapter 19). Recent observations showed that single-nucleotide polymorphisms in the genes *TCF7L2*²¹ and *MTHFS*²² are associated with CKD progression in population-based cohorts.

Phenotypically, diabetic and nondiabetic nephropathies cluster in families, particularly in African Americans. In diabetes mellitus, a family history of CVD or hypertension is associated, respectively, with a twofold or fourfold increase in the risk for development of diabetic nephropathy.

Loss of Renal Mass

The threshold to natural progression after nephron loss is likely to be lowered by the presence of hypertension, obesity, hyperlipidemia, hyperglycemia, and black race. Recent evidence

Figure 75.6 Actuarial renal survival in relation to blood pressure. (Modified from reference 23.)

Figure 75.7 Actuarial renal survival in relation to proteinuria. (Modified from reference 23.)

also points to the impact of episodes of AKI on the decline in kidney function, with the elderly being more susceptible.²⁴

Modifiable Progression Risk Factors

These include systemic hypertension, proteinuria, and metabolic factors. In addition, interest has focused on the contribution of cigarette smoking, alcohol consumption, and recreational drug use to the risk for development of ESRD (see also Chapter 76).

Hypertension

Systemic hypertension is an important cause, consequence, and presenting feature of CKD. It is one of the leading causes of ESRD worldwide,⁶ the second leading cause in the United States after diabetes. Some experimental and epidemiologic studies have shown that sustained hypertension is indeed a significant contributor to the progression of CKD. Strong evidence links the progression of CKD to systemic hypertension in diabetic and nondiabetic nephropathies (reviewed in reference 1). It is believed that the transmission of systemic hypertension into the glomerular capillary beds and the resulting glomerular hypertension contribute to the progression of glomerulosclerosis (Fig. 75.6).

Proteinuria

A large number of studies in patients with diabetic and nondiabetic glomerular disease and nonglomerular diseases confirmed, by multivariate analysis, that heavy proteinuria is associated with a faster rate of CKD progression (Fig. 75.7).^{1,25} Furthermore, reduction of proteinuria by diet, angiotensin-converting enzyme inhibition, or angiotensin receptor blockade predicts a better outcome²⁶ (see also Chapter 76); the extent of reduction in proteinuria is often proportional to the benefit accrued by such intervention on CKD progression. Experimental data suggest that proteinuria may contribute directly to the progression of CKD (see later discussion). The threshold for natural progression attributed to proteinuria appears to be crossed when proteinuria exceeds 1 g/day.

Albuminuria, Chronic Kidney Disease, and Cardiovascular Disease

Urinary albumin excretion rate is independently associated with the presence and severity of CVD in the general population.²⁷

Even low-grade albuminuria (below the current microalbuminuria threshold [albumin to creatinine ratio <3 mg/mmol]) in middle-aged nondiabetic and nonhypertensive individuals is associated with increased CVD risk. The risk associated with albuminuria in the general population matches, and sometimes exceeds, that attributed to better known risk factors of CVD, such as hypertension and hyperlipidemia. Diffuse endothelial and vascular dysfunction may be the common pathway linking albuminuria to the manifestations and prognosis of CKD and CVD (see also Chapter 78). Albuminuria has been linked in a number of studies to underlying systemic atherosclerosis, diffuse vascular stiffness, and maladaptive vascular remodeling.^{28,29}

CKD is now defined as a CVD risk equivalent, and patients with moderate to severe CKD are taken to be in the “highest risk group” for development of CVD.^{1,30} Patients with CVD are also at a higher risk for development of CKD. Overall, these observations may, in part, be explained by the fact that CVD and CKD share many risk factors, including obesity, metabolic syndrome, hypertension, diabetes mellitus, dyslipidemia, and smoking. In addition, CVD may have direct hemodynamic effects on the kidneys that may promote initiation and progression of CKD, including decreased kidney perfusion in heart failure and atherosclerosis of the renal arteries, with subsequent ischemic nephropathy. Evidence is linking faster rate of CKD progression to severe atherosclerotic disease.¹⁸

Renin-Angiotensin System

The links between systemic hypertension, proteinuria/albuminuria, and CVD may be mediated by changes in the RAS in CKD. A number of experimental and clinical data have implicated the RAS in the pathogenesis of hypertension, proteinuria, and renal fibrosis throughout the course of CKD (reviewed in reference 31). Consequently, interventions aimed at inhibition of the RAS have proved extremely effective in slowing the progression of CKD (discussed in Chapter 76).

Glycemia

A number of observations as well as randomized clinical trials have demonstrated during the last 25 years that tight diabetes control can potentially slow the rate of progression of diabetic microvascular complications, including diabetic nephropathy in both type 1 and type 2 diabetes mellitus.^{32,33}

Obesity

Several studies have linked obesity, and the associated metabolic syndrome, with increased risk of CKD. Excessive body weight and a raised body mass index have also been linked to a faster rate of progression of CKD. Anecdotal reports suggest that weight reduction reduces obesity-related renal hemodynamic changes as well as CKD-associated proteinuria. Recent data derived from general population studies suggest that body weight reduction reduces albuminuria, and increased weight gain is associated with its progression.³⁴

Lipids

Dyslipidemia may contribute to glomerulosclerosis and tubulointerstitial fibrosis. A number of studies of diabetic and non-diabetic nephropathies have confirmed by multivariate analysis that dyslipidemia is a risk factor for a faster rate of CKD progression.¹

Smoking

Smoking has been shown to increase the risk of albuminuria as well as that of progression of CKD (reviewed in reference 35). Possible mechanisms whereby cigarette smoking may contribute to kidney damage include sympathetic nervous system activation, hypertension, endothelial injury, and potential direct tubulotoxicity.

Uric Acid

Hyperuricemia has been associated with systemic hypertension, CVD, and CKD³⁶ (see also Chapter 33). Hyperuricemia may cause hypertension and renal injury through crystal-independent pathways, notably a stimulation of the RAAS. In a small Japanese study, hyperuricemic patients with IgA nephropathy had a worse prognosis compared with those with normal serum uric acid levels, and a serum uric acid of 6.0 mg/dl or higher was an independent predictor of ESRD in women. However, a more recent observation from the United States suggested that in patients with CKD, hyperuricemia appears to be an independent risk factor for all-cause and CVD mortality but not for kidney failure.³⁷

Additional Factors Implicated in Progression of Chronic Kidney Disease

- Alcohol and recreational drugs
- Analgesics and NSAIDs
- Lead and heavy metals exposure

MECHANISMS OF PROGRESSION OF CHRONIC KIDNEY DISEASE

The progression of CKD is associated with changes in kidney structure characterized by scarring associated with glomerulosclerosis, tubulointerstitial fibrosis, and vascular sclerosis. Whereas injury to the glomeruli, tubules, interstitium, or vessels may predominate initially, CKD progression is often associated with damage and scarring affecting all structural components of the kidney.

The kidney responds to injury by adaptive changes that lead to remodeling evolving toward either healing and functional recovery or scarring with loss of kidney function and progressive CKD.³⁸ During the last 25 years, considerable progress has been made in the understanding of the pathways leading to healing and recovery and those favoring the progression to scarring and

fibrosis. However, little is known about what determines the kidney's predilection for one or the other pathway.

Healing is characterized by recovery of kidney structure and function. It occurs primarily in AKI when acutely damaged tubules recover from the initial insult and replace lost tubular cells to reconstitute the integrity of the tubules and to restore kidney function. Healing also takes place in acute interstitial nephritis when treatment is instituted early in the course of the inflammatory process, leading to resolution of the inflammatory process and tubule recovery. Healing is also the hallmark of acute postinfectious glomerulonephritis, when the acute glomerular inflammation resolves through the death (apoptosis) of infiltrating leukocytes or their efflux from the glomeruli. Renal function typically recovers within a few weeks from the acute nephritic process.

On the other hand, most forms of chronic kidney damage, such as those induced by diabetes, hypertension, chronic glomerulonephritis, or chronic exposure to infections or nephrotoxins, evolve to progressive scarring with loss of function and CKD. Scarring is characterized by the progressive loss of intrinsic renal cells and their replacement by fibrous tissue made of collagenous extracellular matrix (ECM; Fig. 75.8). This affects the glomeruli (glomerulosclerosis; Fig. 75.9), tubules and interstitium (tubulointerstitial fibrosis; Fig. 75.10), and vessels (vascular sclerosis). In this section, we describe the generic elements of renal scarring and fibrosis in an attempt to identify stages potentially amenable to future therapies.³⁹

Renal Cell Loss, Activation, and Transformation

Loss of intrinsic renal cells is one of the hallmarks of progressive renal scarring. Experimental and clinical models of glomerulo-

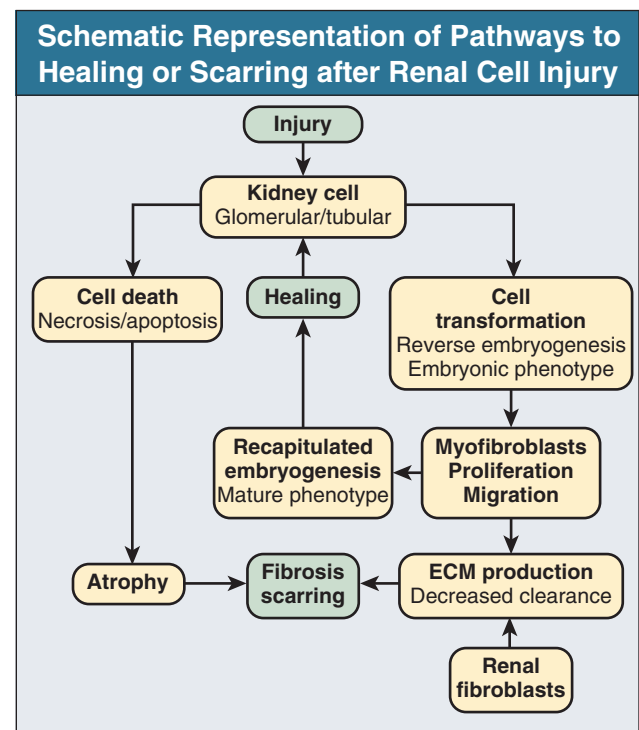

Figure 75.8 Schematic representation of pathways to healing or scarring after renal cell injury. Cell death through necrosis or apoptosis would ultimately lead to renal atrophy and favors replacement by fibrous tissue. Cell injury may lead to dedifferentiation as a step toward recovery and healing.

Figure 75.9 Histologic development of glomerulosclerosis. A, Normal glomerulus. B, Mesangial hypercellularity. C and D, Glomerulosclerosis of increasing severity. Note the tubular atrophy and dilation in B to D, indicating the parallel development of tubulointerstitial scarring.

nephritis display a progressive loss of the fine glomerular capillary structure and the disappearance of the glomerular cellular elements with their replacement by an expanding ECM and fibrous tissue. Loss of glomerular cells through necrosis or apoptosis has been described and can be triggered by a severe glomerular inflammatory process, as in glomerulonephritis with glomerular endothelial and capillary damage, or by continuing damage to glomerular cells, as in subacute and chronic glomerulonephritis affecting the mesangium or the podocytes (Fig. 75.11). Similarly, progressive renal scarring is associated with progressive tubular cell loss and atrophy.

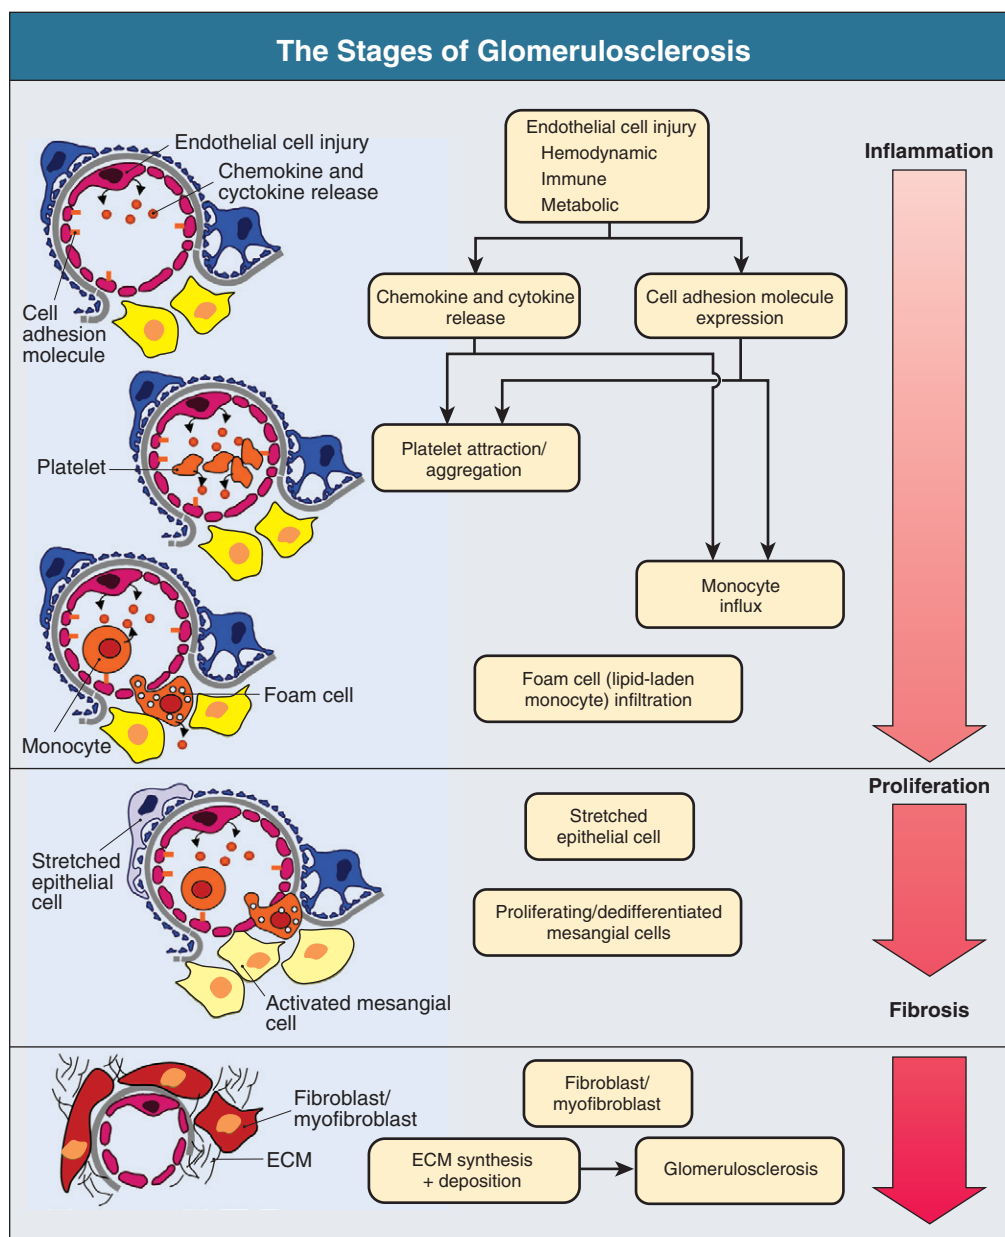

Figure 75.10 Histologic development of tubulointerstitial fibrosis. A, Normal tubulointerstitium. B, Mild tubulointerstitial scarring with tubular atrophy and interstitial edema. C, Segmental interstitial fibrosis. D, Diffuse interstitial fibrosis with tubular atrophy and dilation.

Endothelial Cells

In acute and severe glomerulonephritis, damage to the glomerular endothelial lining triggers further injury. The endothelial capillary lining normally displays protective anticoagulant, anti-inflammatory, and antiproliferative functions.⁴⁰ Damage to the

Figure 75.11 The stages of glomerulosclerosis. ECM, extracellular matrix.

glomerular endothelium transforms this protective cellular layer to a proaggregatory, pro-inflammatory, and mitogenic surface, leading to the accumulation of inflammatory cells and platelets within glomerular capillaries as well as the stimulation of the proliferation of the mesangium. This process bears strong similarities to atherosclerosis with microthrombi formation, infiltration of the glomerular tufts by macrophages and foam cells, and proliferation of the smooth muscle cell equivalent, the mesangial cell. Glomerular endothelial damage can be clearly triggered by an acute inflammatory process but also by a metabolic insult, as in diabetes, or hemodynamic shear stress, as in hypertension.

Mesangial Cells

Mesangial cells are the glomerular capillary equivalent to the smooth muscle cell and in that capacity respond to injury in a similar fashion: death, transformation, proliferation, and migration as well as synthesis and deposition of ECM. Mesangial death through necrosis, lysis, and apoptosis has been well documented

in response to injury. Injury is also followed by the engagement of the mesangial cells in the repair, healing, or scarring process. Dedifferentiation of mesangial cells into an embryonic phenotype with the acquisition of stress fibers and α -smooth muscle actin allows these cells to proliferate, to migrate, and to restore the glomerular structural integrity.³⁸ They also lay down collagenous ECM to seal the wound and to repair structural damage. However, scarring is often characterized by uncontrolled mesangial proliferation and excessive deposition of mesangial matrix. These are the forebears of glomerulosclerosis. Mesangial activation, transformation, proliferation, migration, and ECM synthesis seem to be driven by a number of cytokines and growth factors, including transforming growth factor β 1 (TGF- β 1), platelet-derived growth factor (PDGF), and fibroblast growth factor.⁴¹ These growth factors activate, through their respective mesangial cell surface receptors, a number of intracellular signal transduction pathways. These in turn mediate mesangial events and scarring (see Fig. 75.11).

Podocytes

The relative inability of podocytes to replicate in response to injury may lead to their stretching along the glomerular basement membrane, exposing areas of denuded glomerular basement membrane that would attract and interact with parietal epithelial cells, leading to the formation of capsular adhesions and subsequent segmental glomerulosclerosis.⁴² However, inability of podocytes to replicate was challenged by the hypothesis that glomerular parietal epithelial cells could differentiate into podocytes. It has also been suggested that changes in podocytes' derived growth factors, including vascular endothelial growth factor (VEGF) and PDGF, may also be instrumental in contributing to intraglomerular injury. Capsular adhesions formed by contact between the glomerular basement membrane and the parietal epithelial lining of Bowman's capsule may lead to misdirected filtration with the accumulation of amorphous material in the paraglomerular space and the subsequent disruption of glomerular-tubular junction, resulting in atubular glomeruli. Misdirected filtration may also contribute to tubular atrophy and interstitial fibrosis. Tuft-capsule adhesions may allow the influx of periglomerular fibroblasts into the glomerular tuft, thus contributing to glomerulosclerosis. Podocytopathy and ECM deposition in diabetic nephropathy are believed to be mediated by increased proinflammatory cytokines and growth factor production by podocytes, including VEGF, TGF- β 1, macrophage migration inhibitory factor, and monocyte chemoattractant protein 1.⁴³

Tubular Cells

As with glomerular cells, injury to tubule cells is followed by an attempt at regeneration and repair.⁴⁴ After an acute insult, some tubular cells die through necrosis or apoptosis. Apoptosis has been well documented during the course of experimental and clinical models of CKD. Surviving cells attempt to restore tubule integrity by dedifferentiation into an embryonic phenotype that allows them, through the acquisition of cytoplasmic α -smooth muscle actin and stress fibers, to proliferate, to migrate, and to repopulate acellular tubules. Healing and recovery of renal function ensue. On the other hand, repeated or sustained insult is likely to stimulate sustained epithelial mesenchymal transformation (EMT) of tubule cells into a myofibroblastic phenotype with excessive production and deposition of ECM, contributing to fibrosis. Thus, tubular injury with subsequent activation and transformation can directly contribute to renal fibrogenesis. A number of stimuli have been shown to induce tubular EMT, including cytokines (interleukins) and growth factors (TGF- β 1, epidermal growth factor) as well as advanced glycation products. Also, recent evidence suggests that excessive exposure of tubule cells in culture to albumin, simulating albuminuria, has the capacity to induce EMT. It has been postulated that proteinuria/albuminuria itself is capable of activating the proximal tubules to release proinflammatory mediators and to initiate interstitial inflammation (reviewed in reference 45). Inflammatory cells would lead to more damage and also stimulate resident renal fibroblasts to produce and deposit ECM (Fig. 75.12).

Vascular Cells

Vascular sclerosis is an integral feature of the renal scarring process. Renal arteriolar hyalinosis is present in CKD at an early stage, even in the absence of severe hypertension. Furthermore, these vascular changes are often out of proportion to the severity of systemic hypertension. Vascular sclerosis is associated with progressive kidney failure in glomerulonephritis. Hyalinosis of

Figure 75.12 Development of tubulointerstitial fibrosis. MHC, major histocompatibility complex.

afferent arterioles has been implicated in the pathogenesis of diabetic glomerulosclerosis. Changes in postglomerular arterioles and damage to peritubular capillaries may further exacerbate interstitial ischemia and fibrosis. Ischemia and the ensuing hypoxia are fibrogenic influences that stimulate tubular cells and kidney fibroblasts to produce ECM components and to reduce their collagenolytic activity.⁴⁶

Loss of peritubular capillaries with the associated impaired angiogenesis has been linked in experimental models of renal scarring to a fall in the renal expression of the proangiogenic VEGF. Together with an overexpression by scarred kidneys of thrombospondin, an antiangiogenic factor, this would perpetuate microvascular deletion and ischemia.⁴⁷ The administration of VEGF preserves peritubular capillaries and improves scarring and functional outcome. Finally, the vascular endothelium, adventitia, and pericytes may be a source of interstitial myofibroblasts, contributing to the development of interstitial renal fibrosis.⁴⁸

Recent evidence also points to lymphatic neoangiogenesis in association with interstitial inflammation and progressive renal fibrosis.⁴⁹ Such a process appears to be driven by macrophages that express the lymphangiogenic growth factor VEGF-C. It may play a role in interstitial remodeling as it provides an exit route for inflammatory cells involved in interstitial inflammation.

Inflammation and Infiltration by Extrinsic Cells

Infiltration of the glomeruli and renal interstitium by inflammatory cells is an early and common pathway in the pathogenesis of glomerulosclerosis (see Fig. 75.11) and tubulointerstitial fibrosis (see Fig. 75.12).

Platelets

Platelets and their release products have been detected within glomeruli in experimental and clinical nephropathies. The stimulation of the coagulation cascade is likely to activate mesangial cells and to induce sclerosis. Thrombin stimulates glomerular TGF- β 1 production, leading to production of mesangial ECM as well as that of inhibitors of metalloproteinases. The upregulation within damaged glomeruli of plasminogen activator

Experimental Interventions to Slow CKD with Potential for Clinical Translation			
Target Growth factors	Intervention	Mechanism of Action	Evidence Level
Fibrosis-modulating growth factors (TGF-β1, HGF, BMP-7)	Neutralizing anti-TGF- β 1 antibodies ALK1 (TGF- β 1 receptor) inhibitors Administration of bone morphogenic protein 7 (BMP-7) Administration of hepatocyte growth factor (HGF)	Neutralization of the growth factor (TGF- β 1) Inhibition of receptor-mediated signal transduction Inhibitor of the TGF- β 1-Smad signaling pathway Inhibits nuclear translocation of receptor-regulated Smads and upregulates the expression of Smad corepressors Mediator of TGF- β 1-induced fibrosis	Experimental models of CKD Experimental models of CKD Experimental models of CKD Clinical trials in promoting angiogenesis Experimental models of CKD Phase II clinical trial completed in diabetic nephropathy Experimental models of CKD Used in the treatment of hypertrophic scars and scleroderma Preliminary clinical data in diabetic nephropathy
	Inhibition of connective tissue growth factor (CTGF) Tranilast	 Inhibits TGF- β 1-induced ECM synthesis	 Experimental models of CKD Phase II clinical trial completed in diabetic nephropathy Experimental models of CKD Used in the treatment of hypertrophic scars and scleroderma Preliminary clinical data in diabetic nephropathy
Proliferative growth factors (PDGF, EGF)	Decorin Neutralizing anti-platelet-derived growth factor CR002 (PDGF) antibodies including CR002 PDGF antagonists; aptamers, imatinib mesylate, trapidil	Sequesters TGF- β 1 in the extracellular matrix CR002 monoclonal antibody targeting PDGF-D Direct inhibition of PDGF; imatinib mesylate: tyrosine kinase inhibitor of PDGF transduction	Experimental models of CKD Experimental data indicate potential of CR002 in mesangioproliferative disease Phase I clinical trial completed in MPGN Clinical use limited by cardiotoxicity
	Anti-epidermal growth factor (EGF) antibody Inhibition of epidermal growth factor receptor (EGF-R)	Neutralize EGF action Inhibition of EGF-R by ascofuranone, an isoprenoid antibiotic, that inhibits phosphorylation of EGFR and downstream kinases	Inhibition of renal fibroblast proliferation and collagen expression
Angiogenic growth factors (VEGF)	Administration of vascular endothelial growth factor	To stimulate/restore glomerular and peritubular capillary angiogenesis However, may also stimulate glomerular hypertrophy and albuminuria in models of diabetic nephropathy	Experimental models of CKD Experimental mesangioproliferative GN and diabetic nephropathy
Intracellular transduction pathways	Ras-Raf-Mek-Erk pathway inhibition by: 1: Ras: prenylation inhibitors (statins), prenyltransferase inhibitors farnesylthiosalicylic acid (FTS) 2:Raf and Mek kinase inhibitors Rho kinase inhibition: fasudil	Inhibition of cellular proliferation, differentiation, and apoptosis Interference with cell proliferation, tubulointerstitial fibrosis, and glomerular hemodynamics	Experimental models of CKD Role of statins in progressive clinical CKD not yet defined Experimental models of CKD Phase II studies in ischemic heart disease Fasudil in clinical use in Japan for cerebral vasospasm
	p38 mitogen-activated protein kinase inhibitors	Inhibition of proinflammatory and profibrotic mediators	Experimental models of CKD Clinical trials in rheumatoid arthritis and type 1 diabetes mellitus
	Protein kinase C inhibitors, such as ruboxistaurin	Inhibition of cell growth most evident in diabetic nephropathy	Experimental models of CKD Phase II clinical trials in diabetic nephropathy, reduce albuminuria Experimental models of CKD
Cell cycle inhibitors	Cyclin-dependent kinase inhibitors, such as roscovitine	Inhibition of cell cycle progression	Experimental models of CKD
Immuno suppressive agents	Mycophenolate mofetil (MMF)	Inhibitor of inosine monophosphate dehydrogenase; inhibiting cell proliferation	Experimental models of CKD Used in clinical CKD associated with vasculitis
	Sirolimus (rapamycin)	mTOR inhibitor; interference with cell proliferation by regulating ribosomal biogenesis and protein translation	Variable data in experimental models of CKD but can induce/increase proteinuria Promising in experimental PKD Clinical trials completed in PKD
Other agents	Endothelin antagonists	Reduce cellular proliferation and intraglomerular hypertension; antiproteinuric effect	Experimental models of CKD Clinical trials in diabetic nephropathy Reduce albuminuria in diabetic nephropathy Risk of increased CVD mortality
	Pirfenidone	Inhibits ECM accumulation	Experimental models of CKD Phase II trials in diabetic nephropathy
	Peroxisome proliferator-activated receptor γ agonists	Reduce cell growth, inflammation; antiproteinuric effect	Experimental models of CKD Reduces proteinuria in clinical diabetic nephropathy Risk of increased CVD mortality
	Prolyl hydroxylase domain (PHD) inhibitors, e.g., cobalt chloride, FG-2216	Upregulation of HIF-regulated genes, such as VEGF and EPO	Experimental models of CKD Phase II clinical trials of FG-2216 for treatment of anemia
	Pentoxifylline	Antioxidant	Experimental models of CKD Phase II clinical trials assessing role in proteinuric CKD
	N-Acetylcysteine (NAC)	Antioxidant	Experimental models of CKD Used for AKI prophylaxis in CKD
	Tocopherols	Antioxidant	Experimental models of CKD Tocopherols and α -lipoic acid in clinical trials in CKD

inhibitor 1 is also likely to affect outcome as its inhibition of the proteolytic enzyme plasmin may lead to ECM accumulation and glomerulosclerosis.⁵⁰ Glomerulosclerosis may depend on the balance between thrombotic/antiproteolytic and anticoagulant/proteolytic activities, with a key role played by the plasminogen regulatory system.

Lymphocytes, Monocytes-Macrophages, and Dendritic Cells

Lymphocytes, including helper and cytotoxic T cells, as well as monocytes-macrophages are often identified within damaged glomeruli.⁵¹ It has been postulated that the balance between proinflammatory Th1 and anti-inflammatory Th2 lymphocytes may be a key factor in the resolution or progression of glomerulosclerosis.

The relevance of monocytes-macrophages to the initiation and progression of glomerulosclerosis has been supported by experiments in which depletion of these cells had a protective effect. The release by these cells of cytokines, growth factors, and procoagulant factors is likely to contribute to the pathogenesis of glomerulosclerosis. However, these cells may also contribute to the termination and resolution of the glomerular inflammatory response. Phenotypic and functional macrophage changes may determine the outcome of glomerular inflammation and sclerosis.

Interstitial inflammation is a common precursor of tubulointerstitial fibrosis. The severity of the interstitial inflammatory infiltrate correlates closely with the severity of renal dysfunction and predicts progressive CKD. Interstitial lymphocytes and monocytes have been implicated in the pathogenesis of renal fibrosis with variable degree of involvement. Limited evidence also implicates mast cells, but this area is more controversial.⁵²

Dendritic cells, a subset of cells that play an essential role in immunopathology of the kidney and the crosstalk with other proinflammatory cells including T lymphocytes, also have a central role in the pathogenesis of kidney inflammation in different disease processes.⁵³ In the interstitium, inflammatory infiltrates of B cells, T cells, and dendritic cells form nodular aggregates surrounded by neolymphatic vessels.

Bone Marrow-Derived Cells

Glomerular remodeling (repair-healing or scarring) may depend on the influx of hematopoietic stem cells with the potential for repair or scarring (reviewed in references 54 and 55). The detection of cells displaying embryonic mesenchymal characteristics in glomeruli has led to the hypothesis that hematopoietic stem cells may be involved in normal glomerular cell turnover as well as in the response of glomeruli to injury. Experiments based on bone marrow transplantation have demonstrated the potential involvement of bone marrow-derived cells in normal mesangium turnover and in glomerular repair-repopulation after experimental mesangial injury.

It has also been postulated that bone marrow-derived mesenchymal stem cells may be involved in fibrogenesis by migrating into scarred kidneys and contributing to the pool of fibroblasts.

Extracellular Matrix Processing

Loss of intrinsic renal cells and their transformation into fibroblastic phenotypes are likely to be key events in the pathogenesis of renal fibrosis.⁴⁸ In addition to transformed tubular cells, there is growing evidence that other renal cells, including

vascular endothelial and pericytic cells, have the capacity to transform into mesenchymal myofibroblasts, thus contributing to the renal fibroblastic pool. The other main source of renal fibroblasts is likely to be derived from quiescent renal fibroblasts activated by tubules and inflammatory cells through the release of a range of cytokines and growth factors. Finally, bone marrow-derived stem cells are also thought to participate in renal fibrogenesis.⁴⁸

One of the most potent inducers of EMT and fibroblast activation is thought to be TGF- β 1. This growth factor is thought to be a key factor in wound healing and scarring. It acts through its type 1 and 2 receptors and activates a number of intracellular signal transduction pathways including STATs and Smads. Connective tissue growth factor is one of the TGF- β 1 effectors that enhances TGF- β 1 intracellular signaling pathways. Two growth factors, hepatocyte growth factor and bone morphogenic protein 7 (BMP-7), have so far been shown *in vitro* and *in vivo* to inhibit and even to reverse EMT and to counteract the fibrogenic influences of TGF- β 1. Of interest, uterine sensitization-associated gene 1, the natural antagonist of BMP-7, is abundant in renal tissue and modulates many of the effects of BMP-7 on the kidney.

Fibroblast activation, proliferation, migration, and synthesis of ECM constitute a major step in fibrogenesis and renal scarring. Deposited ECM undergoes quantitative and qualitative changes. For instance, within scarred glomeruli, interstitial type III collagen is deposited. Interstitial fibrosis is associated with excessive deposition of collagens I, III, and IV. The normal homeostasis of ECM turnover is likely to be compromised in the course of renal scarring through excessive synthesis, decreased breakdown, or resistance to breakdown.

Renal ECM breakdown is regulated by a number of collagenolytic enzymes including the matrix metalloproteinases and the plasmin system. These are in turn regulated by a number of inhibitors, such as the tissue inhibitors of matrix metalloproteinases (TIMPs) and the plasminogen activator inhibitors. Decreased matrix metalloproteinase activities or increased TIMPs and plasminogen activator inhibitor 1 activity have been implicated in the deposition of ECM in CKD.

Recent evidence points to another putative pathway to excessive deposition of ECM, namely, resistance to breakdown through structural modification and cross-link of deposited ECM by an enzyme called tissue transglutaminase. This enzyme is upregulated during the course of experimental and clinical nephropathies.⁵⁶ Mice lacking this enzyme have reduced propensity to renal scarring. Synthetic inhibitors of this enzyme have been shown to considerably attenuate experimental renal fibrosis.

A number of potential interventions affecting and modulating different pathways of renal fibrosis are under investigation with variable degrees of promise and success (Fig. 75.13).³⁹

Retarding Progression of Kidney Disease

Christopher Brown, Nabil Haddad, Lee A. Hebert

Progression to end-stage renal disease (ESRD) usually occurs through the mechanisms of the primary kidney disease or by natural progression (see Chapter 75). This chapter focuses on therapies to slow natural progression.^{1,2} The goal is to preserve enough nephron function to avoid the vicious circle of natural progression.

GLOMERULAR FILTRATION RATE LOSS AND THE RISK OF NATURAL PROGRESSION

The tendency for kidney disease to progress independently of underlying etiology does not occur until a certain degree of renal function has been lost, which typically is when the loss of nephron function exceeds 50%. For example, unilateral nephrectomy in living kidney donors does not usually lead to natural progression. However, a normal solitary kidney can be vulnerable to natural progression if it is congenital or acquired early in life or if it is accompanied by hypertension, obesity, hyperlipidemia, or hyperglycemia.^{1,2} Increased risk of natural progression, even though nephron loss is less than 50%, can also occur in persons of African ancestry with hypertensive nephrosclerosis.² Low birth weight, particularly in men, may also cause chronic kidney disease (CKD) and its natural progression, presumably because of inadequate nephron development.³

PROTEINURIA MAGNITUDE AND THE RISK OF NATURAL PROGRESSION

The threshold for natural progression attributable to proteinuria appears to be crossed when proteinuria exceeds 500 mg/day. In most CKD, proteinuria is the single strongest risk factor for progression. An exception is highly selective proteinuria (the urine protein is almost entirely albumin), which can persist in the nephrotic range for more than 10 years without causing renal structural damage.¹

MONITORING KIDNEY DISEASE PROGRESSION

In contrast to natural progression, in which the first sign is increasing proteinuria, the first sign of progression is declining glomerular filtration rate (GFR) in many forms of CKD (Fig. 76.1). Total proteinuria may remain in the normal range, but microalbuminuria is generally present and is the most useful test for the early detection of progression due to the primary CKD, natural progression, or both.⁴

Monitoring Proteinuria Trends

Proteinuria is the strongest single predictor of GFR decline (Fig. 76.2). Furthermore, therapies that reduce proteinuria slow GFR decline, probably through multiple mechanisms (see also Chapter 75). The Modification of Diet in Renal Disease (MDRD) and Ramipril Efficacy in Nephropathy (REIN) trials reported that for each 1g reduction in proteinuria achieved by 4 to 6 months of antiproteinuric intervention, GFR decline was slowed by about 1 to 2 ml/min per year. GFR loss in CKD is typically 4 to 10 ml/min per year.^{1,2} Thus, each reduction of 1 g/day should result in important slowing of GFR decline and delay of ESRD (Fig. 76.3). Figure 76.3 may be an optimistic projection because there is now evidence that as CKD progresses, the rate of decline of GFR accelerates. Nevertheless, the available evidence suggests that substantial benefit can be achieved by measures that reduce proteinuria.

The recommended method for assessing proteinuria is the serial measurement of urine protein-creatinine (PC) ratio (mg/mg) of intended 24-hour urine collections that are at least 50% complete on the basis of their creatinine content. The PC ratios of such collections are generally within $\pm 10\%$ of the PC ratio of complete 24-hour collections.⁵ This recommendation differs from the current National Kidney Foundation Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines, which recommend random spot urine PC ratios. This is because within a given patient, the concordance between random spot PC ratio and 24-hour urine PC ratio is poor, particularly over the moderate proteinuria range (Fig. 76.4).⁵ Also, the random spot urine PC ratio is not a suitable screening test because overestimates and underestimates occur with about equal frequency.⁶ Another advantage of 24-hour urine testing is measurement of dietary sodium and protein intake (see later discussion).

Measurements of total proteinuria and albuminuria are highly correlated in glomerular diseases, and measurement of urine total protein is less expensive than measurement of urine albumin.^{4,5} Proteinuria testing is recommended every 2 to 3 months for those with nephrotic-range proteinuria and every 6 months for those with subnephrotic proteinuria.

Monitoring Glomerular Filtration Rate Trends

In individual patients, it is usually sufficient to monitor GFR trends by serial measurements of serum creatinine. However, one must keep in mind circumstances that can increase serum creatinine by increasing creatinine production (eating cooked meat, creatine ingestion, increased exercise, or increased muscle mass) or decrease creatinine production (vegetarian diet, muscle

wasting, decreased exercise).^{1,2} Serum creatinine can also be spuriously increased by serum ketones (from fasting or poor diabetes control) or by drugs that interfere with tubular secretion of creatinine (cimetidine, trimethoprim). If a chronic progressive change in creatinine production is occurring (e.g., muscle wasting), GFR trends can be monitored by measuring serial 24-hour urine creatinine clearance, which is not affected by change in creatinine production. If creatinine clearance is used, an accurate 24-hour collection is essential.²

The Cockcroft-Gault and MDRD-4 equations provide similar estimates of GFR, especially in the mid range of estimated glomerular filtration rate (eGFR) values (see Chapter 3). The MDRD-4 equation is more easily implemented in clinical laboratories because it does not require knowledge of body weight, it is accurate in many CKD patients, and it takes into account

the influence of age. The last is important in assessing a patient's GFR trend during 10 years or more.^{7,8} MDRD-4 is inaccurate in CKD stages 1 and 2 and in those with high-normal creatinine production (GFR is underestimated) or low-normal creatinine production (GFR is overestimated). During longitudinal testing, MDRD-4 also underestimates GFR decline assessed by iothalamate clearance by about 28%. For those with slowly progressive renal disease, this underestimate can mean a difference of several years between the actual and predicted onset of ESRD.⁷ A newer version of the MDRD equation (CKD-EPI) has been developed but is not yet validated (see Chapter 3).

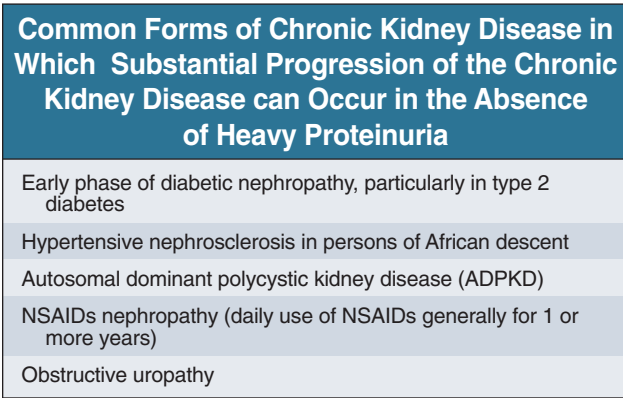

Figure 76.1 Common forms of chronic kidney disease (CKD) in which substantial progression of the CKD can occur. NSAIDs, non-steroidal anti-inflammatory drugs (e.g., serum creatinine increases to >2.0 mg/dl) but proteinuria remains low (e.g., 24-hour urine protein/creatinine ratio <0.3).

Figure 76.2 Relationship between baseline proteinuria and subsequent glomerular filtration rate (GFR) decline. Data from study A of the Modification of Diet in Renal Disease study. (Modified from reference 9.)

Figure 76.3 Average rate of GFR decline due to aging (top curve) in comparison to hypothetical patients each with the onset of a progressive kidney disease at age 25 years but with different rates of GFR decline superimposed on the GFR decline of aging (left panel, men; right panel, women). Note that small differences in GFR decline rate can result in large differences in time to onset of end-stage renal disease (ESRD). GFR, glomerular filtration rate. (Modified with permission from reference 2.)

Figure 76.4 Relationship between 24-hour PC ratio and the ratio (spot PC)/(24-h PC) for the cohorts of study 1 (closed circles) and study 2 (open circles) with PC ratios 0.5 to 3.0. These data are shown in relationship to the expected limits of agreement (dashed horizontal lines) between random spot urine PC ratio and 24-hour urine PC ratio, if they were equally precise in estimating 24-hour proteinuria. These data show that random spot urine PC ratio is an unreliable estimate of 24-hour urine PC ratio.⁶

Measurement of serum cystatin C may provide a better estimate of the GFR than serum creatinine-based measures (see also Chapter 3) but is more expensive. Diabetes, obesity, inflammation and thyroid hormone status can alter cystatin C levels independently of kidney function.¹⁰ The role of cystatin C in CKD management remains to be defined.

THERAPY FOR NATURAL PROGRESSION

Because of the gravity of ESRD and the benefit of even small decreases in CKD progression rate (see Fig. 76.3), a strong argument can be made for an aggressive, multiple risk factor intervention to slow GFR decline.^{1,2} This, however, does not apply for patients with low ESRD risk. This includes corticosteroid-responsive minimal change disease (MCD), a solitary kidney that is normal and acquired in adulthood and not accompanied by other CKD risk factors, hereditary nephritis or thin glomerular basement membrane disease in a normotensive adult whose only renal manifestation is microscopic hematuria, and the elderly with idiopathic and moderately elevated serum creatinine (1.30 to 2.00 mg/dl) and minor proteinuria (24-hour urine PC ratio <1.0) and whose renal parameters have been stable for at least 1 year. The last group is much more likely to die of cardiovascular disease (CVD) than to progress to ESRD.^{1,2}

Recommended therapies in this chapter are listed in Figure 76.5. The recommendations categorized as level 1 (highest) are based on one or more large randomized clinical trials (RCTs) that have documented effects on GFR decline. Level 2 recommendations are based on secondary analysis of the level 1 RCTs, or RCTs that have documented effects on proteinuria but not GFR decline, or RCTs that appear to be of high quality but may not be definitive because of study size.

The goals of progression therapy are (1) to reduce proteinuria as much as possible, ideally to less than 500 mg/day,^{1,2} and (2) to slow GFR decline as much as possible, ideally to about 1 ml/min

Recommended Kidney Protective Therapies According to Level of Recommendation*

Level 1 Recommendations

1. Control blood pressure (BP)
2. ACE inhibitor therapy
3. ARB therapy
4. Combination ACE inhibitor and ARB therapy
5. Renin inhibitor therapy
6. Avoid DHP-CCBs unless needed for BP control
7. Control protein intake

Level 2 Recommendations

1. Restrict NaCl intake/diuretic therapy
2. Control fluid intake
3. NDHP-CCB therapy
4. Control each component of the metabolic syndrome
5. Aldosterone antagonist therapy
6. β -blocker therapy
7. Smoking cessation
8. Allopurinol therapy

Figure 76.5 Recommended kidney protective therapies according to level of recommendation.* *The goal for the chronic kidney disease (CKD) patient is to implement all level 1 recommendations and as many level 2 recommendations as feasible. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; DH-CCB, dihydropyridine calcium channel blocker; NDHP-CCB, nondihydropyridine calcium channel blocker.

per year, which is the rate of GFR decline attributable to aging (see Fig. 76.3).

Level 1 Recommendations to Slow Natural Progression

Control Blood Pressure

The low blood pressure goal is recommended for all CKD patients.^{1,2} On the basis of the relevant RCTs, we suggest a sitting systolic blood pressure in the 120s or lower, if it is tolerated. “Optimal” blood pressure (systolic blood pressure <120 mm Hg) is associated with significantly lower CVD risk than “normal” blood pressure (systolic blood pressure of 120 to 129 mm Hg),² and there is no convincing evidence that systolic blood pressure below 120 mm Hg is harmful if it is well tolerated (not associated with fatigue, lightheadedness, tachycardia, or decline in kidney function).^{1,2} Sitting blood pressure is recommended because it is the position used in the relevant RCTs. Systolic blood pressure is the recommended goal because in the relevant RCTs, achieved systolic blood pressure strongly correlated with GFR decline, but achieved diastolic blood pressure did not. Specifying a goal with both a systolic and diastolic blood pressure component is not recommended. It can be confusing to the physician and the patient and can lead to overtreatment.² Isolated diastolic hypertension probably represents an artifact, particularly in white hypertensives.²

The greater the proteinuria, the greater is the benefit of the low blood pressure goal in slowing GFR decline. Current guidelines do not recommend the low blood pressure goal for those with low-level proteinuria, although the low blood pressure goal does prevent progressive increase in proteinuria compared with the usual blood pressure goal (135/85 mm Hg) and probably further reduces CV risk.^{1,2} Home blood pressure monitoring is recommended to assess whether the patient is achieving the blood pressure goal.^{1,2} Treatment of nocturnal hypertension, assessed by ambulatory blood pressure monitoring, may also provide benefit.²

Antihypertensive drug selection can play an important role in maximizing the CV benefits of hypertension control (see also Chapter 78). For example, in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), diuretic therapy in nonblack hypertensives lowered blood pressure significantly better than angiotensin-converting enzyme (ACE) inhibitors but did not lower cardiovascular (CV) risk more than ACE inhibitors.¹¹ In the Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial (ONTARGET), ACE inhibitors plus angiotensin receptor blockers (ARBs) lowered blood pressure significantly better than ACE inhibitors or ARBs alone but did not lower CV risk better than either drug alone.¹² In the Avoiding Cardiovascular Events Through Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial, ACE inhibitor plus CCB lowered systolic blood pressure comparable to ACE inhibitor plus thiazide diuretic, but the cohort receiving ACE inhibitor and CCB experienced significantly fewer CV events.¹³

The classes of drugs used to lower blood pressure also importantly influence CKD progression.^{1,2} An evidence- and experience-based algorithm for blood pressure control in CKD is shown in Figures 76.6 and 76.7. Delay in achieving the low blood pressure goal increases the risk for progression to ESRD.² If systolic blood pressure is 20 mm Hg or more above goal, two or more antihypertensive agents will usually be needed to achieve blood pressure goal.²

ACE Inhibitor Therapy

This drug class is recommended as first-line therapy in all CKD patients. Although the ALLHAT study suggested that diuretics should be first-line therapy in CKD with low-level proteinuria,² the study protocol did not use ACE inhibitors optimally (with diuretic, if needed), which confounds its interpretation. Also, the benefits of diuretics were seen mainly in black patients. Diuretics as monotherapy may induce metabolic dysfunctions that include hypokalemia, hyperglycemia, hyperuricemia, and stimulation of the renin-angiotensin-aldosterone system (RAS),^{1,2} each of which increases CV risk. However, if the diuretic is used with an ACE inhibitor (or ARB), most of the metabolic dysfunctions associated with diuretic use should be mitigated.^{1,2,14}

Although both ACE inhibitors and ARBs are kidney protective, ACE inhibitors are the first choice because it is not yet clear if ARBs give equivalent cardioprotection.² ACE inhibitors should be used even if the patient is not hypertensive.^{1,2} Measures that may increase ACE inhibitor-associated kidney protection include a low-sodium and reduced-protein diet, diuretic therapy, lower blood pressure goal, and statin therapy.^{1,2} ACE inhibitors are antiproteinuric even in inflammatory glomerulonephritis (GN). ACE inhibitors should be continued even though GFR declines to stage 4 CKD (15 to 29 ml/min per 1.73 m²). To prevent hyperkalemia, dietary potassium restriction and the concomitant use of furosemide and sodium bicarbonate may be indicated.²

CV and renal benefits of ACE inhibitors appear to be a class effect. There is no firm evidence of additional benefits for any particular ACE inhibitor. A plausible argument can be made for the preferential use of ramipril and benazepril, which have relatively long half-lives and strong are inhibitors of tissue ACE, the most important component of the RAS.

Advancing the ACE inhibitor dose to tolerance increases its antiproteinuric effect and decreases the likelihood of aldosterone escape (increasing plasma aldosterone levels during stable ACE inhibitor therapy), which could diminish ACE inhibitor-

associated renoprotection.² ACE inhibitors may be particularly effective in those who are homozygous for the *ACE* gene insertion (I) polymorphism.¹⁵

Although a recent meta-analysis suggested that ACE inhibitors may not have kidney protective effects apart from blood pressure control, that analysis included heterogeneous studies that did not all use ACE inhibitor treatment optimally or have ideal methodologic rigor.²

ARB Therapy

ARBs are protective in the nephropathy of type 2 diabetes and probably in other nephropathies.² ARBs are recommended as first-line therapy in those who are ACE inhibitor intolerant (cough, angioedema, or allergy). In CKD, ARBs may raise serum potassium less than ACE inhibitors.² The highest tolerated ARB dose, up to the maximum recommended dose, is recommended for maximum antiproteinuric effect² and to optimize regression of left ventricular hypertrophy.² ARBs may be especially effective in those who are homozygous for the *ACE* gene deletion (D) polymorphism.¹⁵ There is recent evidence that the ARBs that became available after losartan may have better CV and renal protective effects.

Combination ACE Inhibitor and ARB Therapy

Combined ACE inhibitor and ARB therapy may be more antiproteinuric than ACE therapy inhibitor or ARB alone.¹⁶ However, there is uncertainty about the scientific validity of the COOPERATE study, the only long-term study of combination ACE inhibitor and ARB therapy in CKD.¹⁶

Furthermore, there are puzzling data from the ONTARGET study suggesting that combination ACE inhibitor and ARB therapy increased the risk of renal endpoints, despite achieving lower blood pressure than either ACE inhibitor or ARB therapy alone. One possible explanation is unfavorable outcome when blood pressure is reduced too far in patients with severe atherosclerotic renovascular disease. Combination ACE inhibitor and ARB therapy should therefore be used with caution in those with evidence of advanced atherosclerotic CV disease, but it may still be warranted, especially if there is heavy proteinuria.

Renin Inhibitor Therapy

Aliskiren, a direct renin inhibitor, has been combined with losartan in the Aliskiren in the Evaluation of Proteinuria in Diabetes (AVOID) study in patients with hypertension and diabetic nephropathy, resulting in greater reduction in proteinuria compared with losartan alone; the antiproteinuric effect was independent of its effect on blood pressure. Aliskiren is well tolerated and is a promising agent, although more data are required before its role in CKD with proteinuria can be defined.

Avoidance of Dihydropyridine CCBs

Avoid therapy with dihydropyridine calcium channel blockers (DHP-CBBs) unless they are needed for blood pressure control. DHP-CBBs lowered blood pressure better than ACE inhibitors or β -blockers did; however, in those with hypertensive nephrosclerosis, it led to accelerated GFR decline and increased the risk of a composite endpoint of doubling of serum creatinine, ESRD, or death.^{1,2} The clearest evidence that DHP-CBBs are not kidney protective is the REIN-2 trial, in which nondiabetic proteinuric renal disease patients receiving ramipril were randomized to the usual or a low blood pressure goal. DHP-CBBs (felodipine) was used to achieve the low blood pressure goal. Despite achieving the low blood pressure goal, the DHP-CBBs group did not

Algorithm 1: Initial Antihypertensive Therapy*

Begin ACE inhibitor therapy: Use ARB if ACE inhibitor intolerant. This therapy is indicated for kidney and cardiovascular protection even if hypertension is not present.

If BP not at goal after 2-4 weeks, titrate ACE inhibitor (or ARB) upward to maximally tolerated dose.
Rationale: High dose ACE inhibitor (or ARB) is more cardiovascular and renal protective than lower-dose ACE inhibitor (or ARB).

If BP not at goal after 2 to 4 weeks, an individualized approach is recommended.

Panel A: Add diuretic if one or more of the following is present:

- African ancestry.
- Habitual high salt intake.
- Cardiac systolic or diastolic dysfunction.

Rationale: When the above stated complicate CKD, diuretic therapy is especially helpful in controlling BP and proteinuria. However, diuretic therapy can worsen many aspects of the metabolic syndrome. This needs to be taken into account.

Panel B: If none of the conditions shown in Panel A are present, or if heavy proteinuria is present (e.g., 24-h P/C >2.0):

- Add ARB to the ACE inhibitor patient.
- Add aliskiren (renin inhibitor) to the ARB patient.

Rationale: Intensifying RAAS blockade ("dual therapy") optimizes antiproteinuria therapy. It also lowers BP. However, dual blockade may not reduce cardiovascular risk.

If BP not at goal after 2 to 4 weeks of the Panel A or Panel B interventions:

- Panel A patients: add ARB to ACE inhibitor. If already on ARB (i.e., ACE inhibitor intolerant), add aliskiren.
- Panel B patients: add diuretic.

If BP not at goal after 2 to 4 weeks, reassess the following:

- Medication compliance (are prescribed medications collected from pharmacy?).
- Regular use of "over-the-counter drugs" that can raise BP (decongestants, vasoconstrictive nose spray or eye drops, NSAIDs) or alcohol (more than 2 drinks daily).
- Excessive salt intake (measure 24-hr urine Na or C if on NaHCO_3).
- Sleep apnea.
- New major life stressors.

If the above assessment is unrevealing, consider ambulatory blood pressure monitoring (ABPM). If ABPM confirms that patient's BP is not at goal, proceed to Algorithm 2 (Fig 76.7).

Figure 76.6 Algorithm 1: initial antihypertensive therapy.* *Assumes nonpharmacologic therapy to control blood pressure is in place (see text) and that the patient does not have renovascular hypertension, congestive heart failure, ischemic heart disease, or hypertensive urgency. This approach focuses on blood pressure control in proteinuric nephropathies but is also appropriate for nephrosclerosis, polycystic kidney disease (PKD), and interstitial nephropathies. ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BP, blood pressure; CKD, chronic kidney disease; NSAIDs, nonsteroidal anti-inflammatory drugs; RAAS, renin-angiotensin-aldosterone system.

experience slower GFR decline or proteinuria reduction compared with those maintained at the usual blood pressure goal, despite concomitant ramipril therapy. The mechanism may be that the DHP-CBBs, by causing afferent arteriolar vasodilation, do not reduce glomerular hypertension.^{1,2} Although DHP-CBBs should generally be avoided in CKD management, DHP-CBBs clearly are important in blood pressure management to reduce CV risk; for example, in the ACCOMPLISH trial, ACE inhibitor and DHP-CBBs reduced CV risk more than ACE inhibitor and diuretic did. However, for kidney protection, if a CCB is

needed, the first choice should be a nondihydropyridine CCB (see Fig. 76.6 and later discussion).

Control Protein Intake

Reducing dietary protein intake from the usual level (about 1 to 1.5 g/kg ideal body weight per day) to about 0.7 g/kg ideal body weight per day (low-protein diet) slows GFR decline in those with proteinuria of more than 1 g/day.¹ Another benefit of the lower protein intake is that it slows proteinuria progression in CKD, even in those who at baseline have low-level proteinuria

Algorithm 2: Recommended Approach if Algorithm 1 Fails to Control BP*

Reassess the patient for secondary causes of hypertension, especially:

- Duplex scan of the renal arteries to assess for high-grade unilateral or bilateral renal artery stenosis.
- Plasma renin and aldosterone to screen for primary hyperaldosteronism, Liddle syndrome, and other rare hypertension-inducing disorders, the presence of which can be revealed by this testing (see Chapters 38 and 39). Note that renin levels are not valid in patients receiving aliskiren because this drug directly interferes with the renin assay.
- Consider coarctation of the aorta, particularly in young CKD patients with difficult-to-control hypertension. Recommended screening: Is left arm BP <right arm BP, is leg BP <arm BP, or is there pulse delay between right femoral and right radial artery?

If testing does not reveal a reason for the resistant hypertension, the recommended approach is to individualize. **Note:** β -Blockers are not a recommended part of the algorithm unless the patient has ischemic heart disease, arrhythmia, or other cardiac conditions for which β -blockers are indicated.

Rationale: β -Blockers lower BP but not cardiovascular risk as well as other classes of hypertensive agents. Carvedilol may be an exception. See text.

Panel C: Aldosterone antagonist. This course is recommended if plasma aldosterone levels suggest that appropriate RAAS suppression has not been achieved by dual therapy. Most patients on dual therapy will show plasma aldosterone level at or below the lower range of normal. Thus, if plasma aldosterone is at or above the midrange of normal, consider a trial of an aldosterone antagonist (spironolactone or eplerenone) if serum potassium is normal and eGFR is >30.

Rationale: This class of drugs is an excellent antihypertensive and may have specific antiproteinuria effects via the podocytes. Also, antagonizing aldosterone provides cardiovascular protection. Careful monitoring of serum potassium is essential.

Panel D: Nondihydropyridine calcium channel blockers. This course is recommended if adequate RAAS suppression is present or if eGFR is ≤ 30 . The clinically available drugs are verapamil and diltiazem. The extended-release forms are recommended. These allow for once- or twice-daily dosing.

Rationale: Nondihydropyridine CCBs are effective antihypertensive agents, are well tolerated, and tend to have antiproteinuria effects. This is in contrast to dihydropyridine CCBs, which promote proteinuria.

If BP is not at goal after 2 to 4 weeks, the recommended approach is as follows:

- Panel C patients: add a NDHP-CCB.
- Panel D patients: consider adding an aldosterone antagonist if eGFR >30.
- Panel C or Panel D patients: Additional diuretic therapy may be needed.

If the BP is not at goal after 2 to 4 weeks, add a DHP-CCB to Panels C and D cohorts. Titrate up the dose of NDHP-CCB and DHP-CCB until the BP goal is met. See text for details.

Rationale: The combination of an NDHP and a DHP-CCB is a potent and well-tolerated antihypertensive combination when added to usual antihypertensive regimens, as described above.

After the BP goal is met, it may be possible to decrease some of the antihypertensive meds started earlier. The recommended order in which meds can be discontinued or tapered is diuretic \rightarrow ARB \rightarrow DHP-CCB.

Figure 76.7 Algorithm 2: recommended approach if algorithm 1 fails to control blood pressure.* *If patient is intolerant of or allergic to the drugs recommended in the algorithms, suggested alternatives include ethacrynic acid for thiazide diuretics, aliskiren for ACE inhibitor or ARB, and minoxidil for calcium channel blocker. Carvedilol or doxazosin may be appropriate in algorithm 2 at any point in patients in whom stress may play an important role in their hypertension or in whom BP is particularly labile, in the absence of correctable factors to account for the lability (pseudopheochromocytoma). ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure; CCBs, calcium channel blockers; CKD, chronic kidney disease; DHP-CCB, dihydropyridine calcium channel blocker; eGFR, estimated glomerular filtration rate; NDHP-CCB, nondihydropyridine calcium channel blocker; RAAS, renin-angiotensin-aldosterone system.

(e.g., <250 mg/day).^{1,2} Diets incorporating soy proteins may induce less proteinuria than those composed of only animal proteins.² Dietary protein intake should be monitored periodically, for example, each 4 to 6 months, by measuring urine urea excretion in 24-hour urine collections. For a 70-kg person, ingestion of about 50 g of protein daily would achieve the dietary goal of 0.7 g/kg ideal body weight per day. In such a patient, the 24-hour urine collection would contain about 8 g of urea nitrogen. Monitoring protein intake is particularly important in those who are not achieving their proteinuria goal. Men and those with glomerular disease may particularly benefit from the low-protein diet.² Severe protein restriction should be avoided; in the MDRD study, long-term follow-up of those on a very low protein intake (<0.6 g/kg per day) showed no further reduction in GFR decline but appeared to have an increased risk of death.¹⁷

Level 2 Recommendations to Slow Natural Progression

Restrict NaCl Intake and Diuretic Therapy

A high salt intake (e.g., 200 mmol NaCl/day, 4.6 g sodium, 11.6 g NaCl) can completely override the antiproteinuric effects of ACE inhibitor, ARB, or NDHP-CCB therapy.^{1,2} The recommended NaCl intake in CKD (assuming that renal salt wasting is not present) is about 80 to 120 mmol/day (2 to 3 g Na). The NaCl intake in the average North American adult is about 170 mmol/day (3.9 g Na, 9.9 g NaCl). Salt intake should be monitored periodically (e.g., each 4 to 6 months) by 24-hour urine collection.² With achievement of the goal for salt intake, a complete 24-hour urine collection would have about 80 to 120 mEq of sodium. The monitoring of 24-hour urine sodium content is particularly important in those not achieving the blood pressure or proteinuria goal. In patients receiving NaHCO₃ therapy, urine chloride rather than sodium should be monitored, taking account of concomitant KCl.² High fructose intake (in the form of table sugar or high-fructose corn syrup) should be avoided because it increases renal sodium reabsorption and can worsen blood pressure control.¹⁸

Diuretic therapy improves blood pressure control and reduces proteinuria in those receiving ACE inhibitor or ARB.² Nevertheless, the ideal is to avoid diuretics because of the multiple metabolic dysfunctions, which include hypokalemia, hyperglycemia, hyperlipidemia, and stimulation of the RAAS, all of which are known to increase the CV risk. Furosemide may be more effective than thiazide diuretics with serum creatinine concentration of more than 2.0 mg/dl.

Control Fluid Intake

A retrospective analysis of MDRD study A showed that urine volumes exceeding 2 l/day were associated with faster GFR decline, especially in patients with polycystic kidney disease (PKD).^{1,2} The patients with the higher urine volumes showed higher blood pressure, lower serum sodium, and frankly hypotonic urine, suggesting that they were intentionally taking in excess fluid ("pushing fluids"). Also, in the African American Study of Kidney Disease (AASK) trial, urine volume measured at baseline was the seventh strongest predictor of GFR decline of the 35 baseline predictors tested, predicting GFR decline to the same degree as baseline systolic blood pressure.¹⁹ Excessive fluid intake in a CKD subject may be difficult to excrete and can lead to volume overload. CKD is associated with both impaired concentration and dilution. Thus, one should neither restrict nor push fluids in CKD.

Nondihydropyridine Calcium Channel Blocker Therapy

This class of agents, which includes diltiazem and verapamil, is antiproteinuric and may be renoprotective. NDHP-CCB together with a DHP-CCB is a potent antihypertensive combination when it is used along with other antihypertensive therapies (see Fig. 76.6).^{1,2}

Control Each Component of the Metabolic Syndrome

The metabolic syndrome is defined as any three of the following:

- Blood pressure $\geq 130/85$ mm Hg or requiring antihypertensive therapy.
- Fasting blood glucose concentration >100 mg/dl (5.6 mmol/l) or treatment for hyperglycemia.
- Fasting serum high-density lipoprotein cholesterol level <40 mg/dl for men, <50 mg/dl for women.
- Fasting serum triglycerides ≥ 150 mg/dl or drug therapy needed to control hypertriglyceridemia.
- Waist circumference >40 inches (102 cm) in men or >35 inches (88 cm) in women.

Each component of the metabolic syndrome is a risk factor for CKD progression. Also, the prevalence of microalbuminuria and CKD increases proportionately with the number of components of the metabolic syndrome.

Obesity increases the risk for CKD and is associated with glomerulomegaly, focal and segmental glomerulosclerosis, and proteinuria, which can be progressive. Reducing even moderate obesity can reduce proteinuria. In moderately obese CKD patients (mean body mass index, 32; mean proteinuria, 2.8 g/day), a 4% decrease in body weight during 5 months reduced proteinuria by 31%.²

Management of lipids in CKD is discussed in Chapters 77 and 78. Although definitive evidence of benefit is lacking, we recommend statin therapy to control lipids in CKD patients not on dialysis, in view of their increased CV risk of CKD.

Aldosterone Antagonist Therapy

Spironolactone and the more selective aldosterone antagonist eplerenone have substantial antihypertensive, cardioprotective, and antiproteinuric effects even in low doses (e.g., spironolactone, 25 mg daily) and in the presence of combined ACE inhibitor and ARBs.²⁰ The mechanism may involve benefits of aldosterone blockade on endothelium and the profibrotic effects of aldosterone. If these drugs are used in combination with ACE inhibitor or ARBs, monitoring for hyperkalemia is necessary. Although there are no strong trial data with hard endpoints such as ESRD, the available evidence supports the use of aldosterone antagonists in high-risk CKD patients who have not reached their blood pressure or proteinuria goals despite other therapy (see Fig. 76.7). However, the use of aldosterone antagonists should be restricted to those with an eGFR above 30 ml/min per 1.73 m².²⁰

β -Blocker Therapy

The AASK study showed that β -blocker therapy is more antiproteinuric and slows GFR decline more than DHP-CCB. However, β -blockers increase the likelihood of diabetes and, as monotherapy or combined with diuretic, increase the mortality rate of hypertension management compared with ACE inhibitors plus diuretic.¹⁴ β -Blockers should be used in CKD to manage heart disease but should not be first-line therapy for blood pressure and proteinuria. Carvedilol, which possesses both β -blocker and α_1 -blocker effects, may be better tolerated than metoprolol when it is used in combination with an ACE inhibitor.²

Smoking Cessation

There is strong epidemiologic evidence that cigarette smoking promotes progression of all forms of kidney disease and that this effect may be of greater magnitude in African Americans.²

Allopurinol Therapy

In a placebo-controlled, randomized trial, allopurinol therapy resulted in a 40% lesser increase in serum creatinine during 1 year of follow-up and improved blood pressure control (~13 mm Hg lower systolic blood pressure).² In another trial allopurinol or placebo was administered to 113 subjects with CKD stage 3 for 2 years. There was a slight improvement in the allopurinol group (+1.3 mL vs -4 mL per min per 1.73 m²) and a substantial (70%) reduction in cardiovascular events.²¹ These findings are consistent with an abundance of evidence that serum uric acid elevation is a strong risk factor for the development of CV and renal disease.²² Allopurinol therapy mitigates these risk factors, perhaps by mechanisms beyond lowering of serum uric acid. However, allopurinol can be associated with a severe allergic reaction (Stevens-Johnson-like syndrome). If allopurinol is administered to CKD subjects, the dose needs to be reduced.

Although there is substantial evidence supporting the use of allopurinol in hyperuricemic CKD patients, some experts recommend that allopurinol not be used for asymptomatic hyperuricemia in CKD until better information becomes available because of the risk of severe toxicity.²² A new xanthine oxidase inhibitor, febuxostat, is now available. It is safe in patients allergic to allopurinol and does not need dose adjustment in CKD. To date, severe reactions have not been reported; however, experience in the use of this drug in CKD is limited.

Other Measures to Retard Progression of Chronic Kidney Disease

- Avoid multiple daily doses of acetaminophen, particularly in women, because of the evidence that it is significantly associated with rising serum creatinine during prolonged follow-up.²
- Avoid nonsteroidal anti-inflammatory drugs (NSAIDs) altogether (or, at most, take no more than once or twice weekly) because of their known nephrotoxicity. Daily low-dose aspirin, however, appears to provide net benefit in CKD.²
- Avoid herbal therapy unless the safety of the herb has been proved. Many herbals appear to be nephrotoxic (see Chapter 74).²
- Avoid prolonged severe hypokalemia because it can cause progressive renal interstitial fibrosis.²
- Avoid phosphate cathartics. These can cause acute kidney injury (AKI) and CKD by causing intratubular calcium phosphate deposits.
- Avoid intravenous bisphosphonates in CKD. Some may exacerbate renal failure.
- Avoid oral estrogen in elderly women with CKD. It may promote progression.
- NaHCO₃ to correct metabolic acidosis should be considered because of its anticatabolic effects. Also, the nephrotoxicity of nonselective proteinuria appears to be strongly related to activation of the alternative complement pathway in the renal tubular compartment. NaHCO₃ inhibits this process by raising tubular fluid pH.²

- Control hyperphosphatemia and hyperparathyroidism. In animal models and in human studies, control of hyperphosphatemia slows CKD progression. Also, active 1,25-dihydroxyvitamin D therapy has been found to be potentially antiproteinuric (dipstick protein) in CKD in one *post hoc* analysis of an RCT and by this mechanism might be kidney protective.²

Clinical Evaluation and Management of Chronic Kidney Disease

David C. Wheeler

Although many patients with chronic kidney disease (CKD) progress to end-stage renal disease (ESRD) and require renal replacement therapy, the majority die of nonrenal causes, particularly premature cardiovascular events.¹ Early diagnosis of CKD is therefore important because it provides opportunities to delay progression of CKD (see Chapter 76) and to prevent cardiovascular complications (see Chapter 78).

DEFINITIONS

The U.S. Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines² classify CKD (Fig. 77.1) into five stages (Fig. 75.1). This system, which is based on disease severity rather than cause, was endorsed in modified format by the international Kidney Disease: Improving Global Outcomes (KDIGO) organization.³ Because of the impracticalities of using radioisotopes and 24-hour urine collections, the KDOQI classification system recommends that kidney function be assessed by estimating the glomerular filtration rate (GFR) with an appropriate equation. Two formulae are in common use, one developed by Cockcroft and Gault, the other derived from the Modification of Diet in Renal Disease (MDRD) study (see Chapter 3).⁴ Although standardization of creatinine assays remains an issue, the KDOQI staging system provides a useful framework for the management of CKD.

CLINICAL PRESENTATION

Early diagnosis of CKD with the introduction of an algorithm-based disease management plan may slow the rate of decline of kidney function and reduce cardiovascular risk.⁵ Many patients with CKD are known to health care professionals because they are receiving treatment for hypertension, cardiovascular disease, or diabetes. They may be identified because an elevated serum creatinine level or urinary abnormality is detected at routine follow-up. Unfortunately, others remain undiagnosed until they present with symptomatic acute or chronic kidney disease or with a cardiovascular event.

Evaluation of the Patient with Suspected Chronic Kidney Disease

The detection of an estimated GFR (eGFR) of less than 60 mL/min in a patient in whom renal function was previously unknown or normal requires a history and examination with attention to the blood pressure and urinalysis (for protein and blood) to assess whether the disease is acute or chronic. Imaging of the

kidneys by ultrasound is useful as small kidneys suggest chronic disease.

Proteinuria is an important diagnostic and prognostic marker, and its presence indicates a higher risk for both progression of kidney disease and cardiovascular complications.⁶ Measurement of proteinuria in a 24-hour urine collection has been largely abandoned in favor of the “spot” urine albumin/creatinine ratio, although an argument can be made for timed urine collections (see Chapter 76). Dipstick urinalysis and urine culture are also recommended.⁷ Workup of hematuria is discussed in Chapters 4 and 59.

Blood pressure should be checked in all patients. Those with stage 3 to stage 5 CKD need to be assessed for other complications, such as dyslipidemia, anemia, and the biochemical abnormalities that characterize the CKD–mineral bone disorder.

When to Refer to the Nephrologist

Although management of patients with early nonprogressive CKD is increasingly becoming the responsibility of primary care physicians, nephrologists need to assess those individuals likely to progress to ESRD and to require renal replacement therapy. Criteria for referral are included in management algorithms, such as those developed by the U.K. National Institute for Clinical Excellence (NICE; Fig 77.2). Such criteria are not absolute but should provide a guide to the primary care physician as to which patients are likely to benefit from secondary care. Unfortunately, because CKD is not associated with symptoms in the early stages, a substantial proportion of such patients are referred late, often when they need dialysis. Late referral is often avoidable,⁸ particularly among patients with known CKD, and may be due to the lack of recognition by physicians of the nonlinear relation between serum creatinine and GFR. In other cases, late referral is unavoidable because the patient may have had a truly silent illness or an acute presentation of a disease that causes a rapid decline in kidney function.

Late presentation is disadvantageous as it limits the time for patients to select the mode of dialysis or to be listed for “preemptive” kidney transplantation. Furthermore, because an arteriovenous fistula takes weeks to mature, patients presenting late are required to start hemodialysis using central venous catheters. Catheters are prone to infectious complications and inevitably damage central veins, leading to thromboses and stenoses, which may be manifested at a later stage when venous return from one or the other arm is increased by the subsequent construction of an arteriovenous fistula (see Chapter 87).⁹ Late presentation of CKD precludes treatment of uremic complications, such as

hypertension and anemia,¹⁰ both of which contribute to cardiovascular damage, which may ultimately limit life span.¹¹ These factors compound psychological stress, making it difficult for the patient to come to terms with the illness. Importantly, late presentation is associated with a worse prognosis,¹² and the cost of initiating dialysis in ESRD patients presenting late is higher than for those in whom dialysis is initiated electively.¹³

CLINICAL MANIFESTATIONS

A detailed discussion of the complications of CKD is provided in Chapters 78 to 85. With the exception of hypertension, there are usually few clinical manifestations during CKD stages 1 and 2 (GFR >60 ml/min per 1.73 m²), the presence of proteinuria or hematuria being largely dependent on the underlying cause of kidney disease. Other complications (discussed in the following sections) tend to develop progressively as GFR declines below 60 and in particular below 30 ml/min per 1.73 m² (i.e., during stages 4 and 5 CKD).

Hypertension

Between 50% and 75% of individuals with CKD stages 3 to 5 have hypertension (if it is defined as a systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥80 mm Hg).¹⁴ Casual clinic blood pressure is useful, but ambulatory monitoring correlates better with cardiovascular outcomes and is particularly informative if there is suspicion that readings taken in the

hospital are not representative. In patients with atherosclerotic vascular disease and CKD, the presence of renal artery stenosis should be considered (see Chapter 37).

Control of blood pressure both slows the rate of decline of renal function (see Chapter 76) and reduces cardiovascular complications. All classes of antihypertensive agent can be used in CKD patients, although agents blocking the renin-angiotensin system (RAS) may provide better renoprotection (see Chapter 76). Multidrug regimens are usually necessary to achieve blood pressure control, and most recommendations suggest targeting lower blood pressures (125/75 mm Hg), especially in those with diabetes or proteinuria.¹⁴ Lifestyle modifications should be encouraged (see Chapter 34). Fluid retention occurs in CKD stages 3 to 5, and a diuretic can be included in the antihypertensive regimen. In general, thiazides are recommended in patients with CKD stages 1 to 3 and loop diuretics in those with more severely impaired kidney function.¹⁴ Potassium-sparing diuretics can be associated with hyperkalemia in CKD stages 4 and 5 as well as in subjects receiving angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs). The available evidence supports a target blood pressure below 130/80 mm Hg for most CKD patients not receiving dialysis but below 125/75 mm Hg for those with a urinary protein excretion of more than 1 g/24 hours.¹⁴

Dyslipidemia

Patients with CKD stage 3 frequently develop dyslipidemia with elevated plasma triglycerides and low high-density lipoprotein cholesterol due to the accumulation of very low density lipoprotein particles and a disturbance in the maturation of high-density lipoprotein.¹⁶ Total and low-density lipoprotein cholesterol levels are generally normal but may be low in patients with concomitant inflammation and malnutrition.¹⁷

Current guidelines for the treatment of dyslipidemia in CKD patients recommend extrapolation of treatment thresholds and targets from non-CKD populations.¹⁶ Nevertheless, whereas *post hoc* analysis of large randomized controlled trials suggests that statin therapy may benefit patients with CKD stage 3 with vascular disease,¹⁸ to date there is no robust evidence to suggest that these drugs benefit CKD patients without overt vascular disease or those with more advanced stages of CKD. Furthermore, the risks for myopathy with the use of fibrates and statins is increased

Criteria for Definition of Chronic Kidney Disease

Kidney damage for ≥3 months, as defined by structural or functional abnormalities of the kidney, with or without decreased GFR, that can lead to decreased GFR, manifest by either:

- Pathologic abnormalities
- Markers of kidney damage, including abnormalities in the composition of blood or urine, or abnormalities in imaging tests
- GFR <60 ml/min/1.73 m² for ≥3 months, with or without kidney damage

Figure 77.1 Criteria for definition of chronic kidney disease. GFR, glomerular filtration rate. (Modified from reference 15.)

Figure 77.2 Suggested criteria for referral of patients with chronic kidney disease (CKD) to a nephrologist. ACR, albumin to creatinine ratio; eGFR, estimated glomerular filtration rate; PTH, parathyroid hormone. (Modified from NICE CKD guideline.)

Suggested Criteria for Referral of Patients with Chronic Kidney Disease to a Nephrologist		
New Diagnosis	Stage 3	Stage 4
eGFR <30 ml/min/per 1.73 m ²	eGFR falling by >4 ml/min per year	eGFR <20 ml/min per 1.73 m ²
Hemoglobin <11g/dl	eGFR < 50 ml/min in patient younger than 50 years	eGFR falling by >4 ml/min per year
K ⁺ >6 mmol/l	Hemoglobin < 11 g/dl	Hemoglobin <11 g/dl
Ca <2.1 mmol/l	K ⁺ >6 mmol/l	K ⁺ >6 mmol/l
Pi >1.5 mmol/l	Ca <2.1 mmol/l	Ca <2.1 mmol/l
PTH >3× upper limit normal	Pi >1.5 mmol/l	Pi >1.5 mmol/l
Hematuria		PTH >3× upper limit normal
Urine ACR >30 mg/mmol		
Suspected renovascular disease		

in CKD. Fibrate dosage should therefore be reduced in patients with CKD stages 3 and 4 and fibrates should be avoided in CKD stage 5. Statins should be initiated with low starting doses because of drug accumulation.¹⁶

Anemia

Anemia is common in CKD stages 3 to 5 and is caused by a relative deficiency of erythropoietin (EPO), although reduced availability of iron and chronic inflammation are frequent contributory factors.¹⁹ Anemia may contribute to cardiac dysfunction by increasing cardiac output and may thereby exacerbate left ventricular hypertrophy. Although reversal of anemia with erythropoietin has been associated with regression of left ventricular hypertrophy,²⁰ there is currently no evidence that treatment is associated with an improved longer term cardiac prognosis, although its use may be associated with better quality of life.²¹ Debate remains as to the optimal target range of hemoglobin concentrations, with most guidelines recommending a level of 11 to 13 g/dl (see Chapter 79).²² Partial correction of anemia does not accelerate the decline of renal function but may necessitate increases in antihypertensive therapy.²³

Bone and Mineral Metabolism

Hyperphosphatemia together with a deficiency of 1,25-dihydroxyvitamin D₃ contribute to secondary hyperparathyroidism and ultimately to the development of renal bone disease. These biochemical and endocrine changes, in association with the closely related histologic abnormalities of bone and soft tissue calcification, are collectively termed the CKD-mineral bone disorder.²⁴ Bone disease may already be manifested in CKD stage 3 and is well established in ESRD, even though the subject is often asymptomatic (see Chapter 81). Prevention of secondary hyperparathyroidism requires dietary phosphate restriction and administration of phosphate binders.²⁵ Patients are also prescribed biologically active vitamin D (e.g., calcitriol) or vitamin D prohormones that are converted to active dihydroxy compounds in the liver (e.g., 1 α -hydroxyvitamin D₃).²⁶ Many patients with CKD stages 3 and 4 are also deficient in 25-hydroxyvitamin D₃,²⁷ and oral replacement with parent vitamin D₃ (cholecalciferol) may increase plasma levels of the 1,25-dihydroxy derivative.²⁸

Metabolic Acidosis

The metabolic acidosis associated with CKD is caused by failure of hydrogen ion excretion and may be compounded by bicarbonate loss, particularly in interstitial kidney diseases and the accumulation of organic acids. Clinical symptoms from acidosis are rare until patients reach CKD stage 5, when dyspnea may occur. Other causes of dyspnea in advanced CKD, including anemia and pulmonary edema, should always be considered. Acidosis aggravates hyperkalemia, inhibits protein anabolism, and accelerates calcium loss from bone where the hydrogen ions are buffered.²⁹ There is also emerging evidence that correction of metabolic acidosis slows progression of renal disease.³⁰ Severe metabolic acidosis (e.g., serum bicarbonate <20 mmol/l) associated with symptoms in a patient with CKD stage 5 is an indication to start dialysis. If dialysis is not immediately available, oral sodium bicarbonate in a dose up to 1.2 g four times daily may be considered, but sodium loading may aggravate hypertension.

Malnutrition

Malnutrition is common among patients on dialysis but also occurs in CKD stages 4 and 5 (see Chapter 83) and is associated with an increased risk for death.¹⁷ The causes are multifactorial and include anorexia, acidosis, insulin resistance, inflammation, oxidative stress, and urinary protein loss. Biochemical indicators include a decrease in serum albumin, transferrin, and cholesterol. Weight should be monitored in patients who progress to CKD stages 4 and 5. Serum creatinine concentrations, which in part reflect muscle mass, may stop rising despite a progressive loss of kidney function because of compromised nutritional status. If patients do not readily respond to dietary supplementation, initiation of dialysis should be considered.

Sodium and Water Retention

Sodium handling by the kidney is altered in CKD (see Chapter 8), although plasma sodium concentrations are generally within the normal range. As GFR falls, sodium homeostasis is initially maintained because a greater proportion of sodium and water filtered by the glomerulus is excreted as a result of reduced tubular reabsorption (glomerulotubular balance). One of the earliest effects of CKD is to limit the ability of the kidney to compensate for large changes in sodium and water intake. Although water excretion in healthy individuals can vary from about 20 to 1500 ml/h, depending on hydration status, this range becomes restricted in CKD. Excessive oral water intake may lead to dilutional hyponatremia, and in those whose daily fluid intake exceeds 2 liters, it may accelerate progression of CKD (see Chapter 76). As kidney function declines, most patients develop sodium retention and extracellular volume expansion. They may complain of ankle swelling or shortness of breath as a result of pulmonary edema. Restriction of dietary sodium intake to 2.4 g (100 mmol) per day may help alleviate such symptoms and control the associated increase in blood pressure. Salt substitutes containing potassium should be avoided because of the risk for hyperkalemia.

Potassium

Hyperkalemia may develop in CKD stages 4 and 5 and can be managed by dietary restriction to less than 60 mmol potassium daily. Patients with CKD may tolerate higher serum potassium concentrations without electrocardiographic changes or arrhythmias than those with acute kidney injury (AKI), but this is not a consistent feature, and hyperkalemia should always be actively managed (see Chapter 9). Acute reductions in serum potassium are best achieved by glucose and insulin infusion; sodium bicarbonate is less effective in the setting of impaired renal function. Oral resins (such as Kayexalate with sorbitol) are widely used in some countries but may cause gastrointestinal upset and can raise blood pressure because of sodium retention. Dialysis may be required acutely if the serum potassium concentration is markedly elevated (levels >6.5 mmol/l). For chronic management of hyperkalemia, dietary potassium restriction and loop diuretics may be required.

Endocrine Abnormalities

Thyroid Hormones

Total plasma thyroxine (T₄) levels may be low, with an associated increase in triiodothyronine (T₃) as a result of impaired

conversion of T₃ to T₄. Loss of thyroid-binding globulin in urine may further lower total circulating T₄ concentrations.³¹ However, patients do not become clinically hypothyroid, and measurement of thyroid-stimulating hormone remains a reliable diagnostic test for hypothyroidism in CKD.

Growth Hormone

Plasma growth hormone levels may be elevated in patients with CKD stage 5 because of delayed clearance and alterations in hypothalamic-pituitary control.³² In children, growth retardation may result and can be corrected by treatment with exogenous recombinant growth hormone given in supraphysiologic doses.³³

Insulin

Decreased clearance of insulin is balanced by increased peripheral resistance to the effects of the hormone. As a result, there are usually no clinical manifestations, and patients are not particularly prone to hypoglycemia. However, in patients with diabetes, these effects may lead to a falling requirement for insulin as kidney function declines (see Chapter 31), a trend that may be reversed by the initiation of dialysis.³⁴

Sex Hormones

Males Prolactin levels are elevated in CKD stage 5 and may contribute to gynecomastia and sexual dysfunction. Testosterone levels are often low-normal, and gonadotropins may be raised, implying testicular failure.³⁵ This is accompanied by poor spermatogenesis, leading to low sperm counts and reduced fertility. It may be appropriate to prescribe androgen replacement treatment if testosterone is unequivocally low, not least because this may help prevent osteoporosis or erectile dysfunction.³⁶ Erectile dysfunction is also common in the absence of testosterone deficiency and may result from neurological, psychological, and vascular abnormalities. Treatment with phosphodiesterase type 5 inhibitors, such as sildenafil citrate, may be appropriate if there is no evident cardiovascular disease.

Females The pituitary-ovary axis may be disturbed in CKD stages 4 and 5.³⁷ Although luteinizing hormone levels are raised, the normal pulsatile release and the preovulation surge are absent. Cycles may be irregular or anovulatory and associated with amenorrhea. Raised prolactin levels may also contribute to infertility. Nevertheless, conception can occur, and increasingly there are successful pregnancy outcomes (see Chapter 43).

Immunity

Infection is the second most common cause of death after cardiovascular disease in the patient with ESRD, which is due to CKD being a state of chronic immunosuppression³⁸ with defects in both cellular and humoral immunity (see Chapter 80).

T-cell responses to *de novo* antigens are deficient, partly because of impaired antigen presentation by monocytes. Neutrophil activation is defective, and although serum immunoglobulin levels are normal, antibody responses to immunization are poor. In practical terms, this is a problem in immunizing the CKD patient against hepatitis B and other T cell-dependent antigens, such as pneumococcus species and *Haemophilus influenzae* type b (see Chapter 80).

Patients with CKD have an increased susceptibility to bacterial infection (particularly staphylococcal), increased risk of reactivation of tuberculosis (typically with a negative tuberculin skin

test response), and failure to eliminate hepatitis B and C viruses after infections. CKD patients should be immunized against hepatitis B as early as is feasible in an effort to maximize the chances of seroconversion.³⁹

Immunization is still worthwhile in patients presenting with CKD stage 5, but an intensified regimen is recommended (see Chapter 80).

Psychological Manifestations

Anxiety and depression are common in patients with severe CKD and are due to the loss of health and lifestyle changes. Management consists of education and counseling. Short-term antidepressant therapy may help, and some patients benefit from night sedation, particularly during hospital admissions.

Other Complications of Chronic Kidney Disease

CKD patients, particularly those with stage 5 disease, may develop a bleeding diathesis (see Chapter 80), neurologic problems including uremic encephalopathy (see Chapter 82), and dermatologic manifestations (see Chapter 84). Uremic pericarditis may occur in CKD stage 5 and can usually be detected clinically by the presence of a pericardial rub. Administration of anticoagulants to such patients may lead to hemorrhage into the pericardial cavity, causing life-threatening tamponade.

MANAGEMENT OF CHRONIC KIDNEY DISEASE STAGES 4 AND 5

The management of a CKD patient according to the stage of disease is shown in Figure 77.3. For subjects with CKD stage 5 who have symptoms consistent with advanced uremia, dialysis treatment should be initiated. Earlier presentation to a nephrologist increases opportunities to treat complications and to prepare patients for renal replacement therapy. To optimize the management of such individuals, many centers observe patients with CKD stages 4 and 5 in clinics where care is delivered by a multidisciplinary team, including the nephrologist, surgeon, nurse, social worker, dietitian, and psychologist.

Treating the Uremic Emergency

For patients presenting with symptomatic uremia, the priority is to deal with life-threatening complications, such as hyperkalemia, pulmonary edema, metabolic acidosis, encephalopathy, and pericarditis. The uremic emergency can be the initial presentation of either AKI or ESRD resulting from CKD, but the immediate management is the same. Patients presenting with uremic emergencies should be admitted to an intensive care unit or to a high-dependency area. Here, the nephrologist determines treatment priorities, optimizes composition and timing of dialysis, monitors complications, and oversees the medications.

Acute Kidney Injury Versus Chronic Kidney Disease

An important issue is to distinguish acute from chronic kidney disease. There may be hints of a past history of kidney problems (e.g., hypertension, proteinuria, microscopic hematuria) or symptoms suggestive of prostatic disease. The physical examination is not usually helpful, although skin pigmentation (Fig.

Management Plan for Patients with Chronic Kidney Disease, According to Stage				
KDOQI Classification	GFR (ml/min)	Typical Serum Creatinine in 65-kg Subject	Consequences	Actions to Consider
3	30–59	2mg/dl (170 μ mol/l)	Hypertension, secondary hyperparathyroidism	6-monthly eGFR initially 12-monthly eGFR if stable Annual Hb, K, Ca, P Treat hypertension Immunize against hepatitis B
4	15–29	4 mg/dl (350 μ mol/l)	Plus anemia, hyperphosphatemia	3-monthly eGFR initially 6-monthly eGFR if stable 6-monthly Hb, K, Ca, P, and PTH Start phosphate-restricted diet and phosphate binders Correct vitamin D deficiency Start vitamin D analogue Plan renal replacement therapy, including vascular access
5	<15	8 mg/dl (700 μ mol/l)	Plus sodium and water retention, anorexia, vomiting, reduced higher mental function	Plan elective start of dialysis or preemptive renal transplant
5	<5	17 mg/dl (1500 μ mol/l)	Plus pulmonary edema, coma, fits, metabolic acidosis, hyperkalemia, death	Start dialysis or provide palliative care

Figure 77.3 Management plan for patients with chronic kidney disease (CKD), according to stage. The table gives a rough guide to the level of serum creatinine corresponding to each stage of CKD in a typical 65-kg subject and shows the approximate timing of the anticipated clinical problems and interventions required as CKD progresses. At each stage, the action plan for the previous CKD stage should be followed if it has not already been initiated. eGFR, estimated glomerular filtration rate; PTH, parathyroid hormone.

Figure 77.4 Uremic pigmentation. Diffuse brown pigmentation as seen here suggests chronic kidney disease rather than acute kidney injury.

77.4), scratch marks, left ventricular hypertrophy, and hypertensive fundal changes favor a chronic presentation.

The renal ultrasound examination is the most useful distinguishing test. Small kidneys with reduced cortical thickness, showing increased echogenicity, scarring, or multiple cysts, suggest a chronic process. Blood tests are less helpful unless they indicate evidence of an acute illness that may be the cause of kidney failure, such as systemic vasculitis or multiple myeloma. A normochromic normocytic anemia is usual in CKD but may

also be a feature of acute systemic illnesses, so it is not discriminatory. Low serum calcium and raised phosphate levels also have little discriminatory value, but normal levels of parathyroid hormone are more in keeping with AKI. Patients with grossly abnormal biochemical values (e.g., blood urea nitrogen >140 mg/dl, serum creatinine 13.5 mg/dl (>1200 μ mol/l), blood urea >300 mg/dl (>50 mmol/l) who appear relatively well and are still passing normal volumes of urine are much more likely to have chronic than acute kidney disease.

Establishing the Cause of Chronic Kidney Disease

Establishing the cause of CKD is important as there may be a treatable condition, and those with genetic causes, such as adult polycystic kidney disease (PKD), may require appropriate counseling. Some kidney diseases may also recur after transplantation, and an accurate diagnosis may therefore influence later management. However, the cause of CKD is often unclear, with an unhelpful past medical history, minimal abnormalities of urinalysis, and small kidneys on ultrasound, in which case investigation should not be pursued relentlessly because the implications for treatment are often minimal. Attempting to obtain biopsy material from small kidneys is also risky, and if biopsy is performed, it may show only nonspecific chronic scarring.

Minimizing Progression of Chronic Kidney Disease

Delay or prevention of the progression of kidney failure is a management priority in CKD. In some cases, the underlying cause can be modified or arrested. In all patients, there will be modifiable factors, most notably hypertension (see Chapter 76).

Unexpected Deterioration of Kidney Function

CKD patients may require reassessment if kidney function suddenly declines faster than predicted during follow-up (Fig. 77.5); the possible causes are listed in Figure 77.6. Because subjects with CKD frequently have impaired urinary concentrating ability, the most common cause is volume depletion due to the overzealous use of diuretics, insufficient fluid intake in hot weather, diarrhea, or vomiting. Dehydration substantial enough to cause a rise in serum creatinine may not cause symptoms, although there may be a fall in body weight of at least 3 kg and a postural drop in blood pressure. Kidney perfusion can also be compromised by heart failure, myocardial infarction, and tachyarrhythmias and may be affected by drugs, including non-steroidal anti-inflammatory drugs (NSAIDs), ACE inhibitors, and ARBs. Other common causes include acute interstitial

nephritis (see Chapter 60), obstructive nephropathy (see Chapter 58), and intercurrent infection.

Additional causes include hypercalcemia, which may be caused by the coadministration of high doses of vitamin D compounds and calcium-containing phosphate binders; accelerated-phase hypertension; and renal vein thrombosis. The clinician should also be alert to the possibility of relapse of a treated underlying disease.

Assessing Stage of Chronic Kidney Disease and Preparation for Renal Replacement Therapy

Despite all attempts to optimize the management of CKD, many patients will progress to ESRD. The KDOQI staging system (see Fig. 75.1) provides management guidelines according to CKD stage (see Fig. 77.3). In CKD stage 3, prophylaxis against secondary hyperparathyroidism should be started by restricting dietary phosphate; if this fails to control phosphate levels, prescription of oral phosphate binders is appropriate (see Chapter 81). Patients should be checked for deficiency of 25-hydroxyvitamin D₃, and ergocalciferol or cholecalciferol should be commenced if deficiency is shown. Immunization against hepatitis B should be performed. Anemia and iron status should be evaluated and treated or corrected, if necessary (see Chapter 79).

At a GFR of 15 to 20 ml/min (late stage 4 or stage 5), patients should receive education and counseling to aid their selection of the most appropriate renal replacement modality. If hemodialysis is the preferred option, an arteriovenous fistula should be constructed, remembering that it may take 8 to 12 weeks for veins to become adequately arterialized before needling can be attempted (see Chapter 87). Because early kidney transplantation improves long-term outcome,⁴⁰ patients should be assessed for their suitability and, when feasible, activated on the waiting list before dialysis is commenced. This maximizes the chances of the potential recipient remaining in reasonably good health. The availability of a live donor should be explored to increase the chances of preemptive transplantation before the patient begins dialysis.

The decision to start dialysis is generally considered in any patient with CKD stage 5 who develops uremic symptoms, shows evidence of malnutrition, or develops life-threatening complications of CKD, such as pericarditis, hyperkalemia, acidosis, or fluid overload (see Chapter 86). The case for starting dialysis earlier than stage 5 is not strong,⁴¹ but all patients with CKD stages 4 and 5 are best monitored in a multidisciplinary specialist clinic. A plan for assessment of such patients is provided in Figure 77.7.

CONSERVATIVE MANAGEMENT OF TERMINAL UREMIA

There will be patients for whom dialysis is considered inappropriate and others who decide to discontinue treatment. The decision not to initiate dialysis should be made, if possible, in consultation with the patient and family long before the need arises, preferably in the context of a multidisciplinary clinic (see Chapter 86). The patient should be educated about the expected benefits of dialysis as well as its complications and cost (in terms of inpatient stays, travel time, and lifestyle restrictions). One compelling argument not to offer dialysis to elderly patients with high levels of associated comorbidity is that such individuals are unlikely to benefit in terms of life expectancy.⁴² It may also be

Figure 77.5 Acute decline in kidney function in a patient with chronic kidney disease (CKD). Serum creatinine plot for a 58-year-old man with CKD secondary to diabetic nephropathy. An exponential increase over time is seen between 2000 and 2004. However, an abrupt rise occurs in April 2005, when the patient receives contrast medium for coronary angiography without prior hydration. The patient's kidney function never recovered to the previous baseline, and he began hemodialysis in December 2005.

inappropriate to offer dialysis to patients with other comorbid conditions that lead to major limitations or limit life span, such as malignant disease.

In the context of a uremic emergency, when the background history may not be readily available and the patient's premorbid state is unknown, dialysis treatment should not be withheld, particularly when dialysis may provide symptomatic relief. However, subsequently, withdrawal of dialysis or death while on dialysis treatment may be traumatic for both the patient's family and staff. The legal issues are complex and may vary in some respects from country to country, but it is always a requirement for patients to make the decision not to receive or to discontinue dialysis when they are fully informed and able to do so.

Properly managed, death from uremia should be free of suffering. One must ensure that the patient is comfortable with the decision and that family members are understanding and supportive. Symptoms such as dyspnea from pulmonary edema and acidosis are best controlled with an opiate infusion and nausea with regular chlorpromazine or ondansetron. Pain is often underestimated as a symptom of terminal uremia and should be actively managed, usually with opiates. The mouth can become dry and crusted from mouth breathing, and regular mouth washes and gum care should be offered. Pruritus can be managed by cooling the skin and by application of emollients. Myoclonic jerks are distressing and may be reduced by prescription of benzodiazepines.

Cardiovascular Disease in Chronic Kidney Disease

Peter Stenvinkel, Charles A. Herzog

The life span of patients with chronic kidney disease (CKD), particularly those with end-stage renal disease (ESRD), is reduced. In the United States, the all-cause mortality rate of prevalent dialysis patients in 2006 was 221 deaths per 1000 patient-years, 41% attributable to cardiac causes.¹ Diminished estimated glomerular filtration rate (eGFR) is a powerful graded, independent predictor of cardiovascular morbidity and mortality² (Fig. 78.1) and all-cause mortality.³ Even subtle kidney dysfunction, as suggested by albuminuria, increases cardiovascular risk,⁴ as it may reflect microvasculature health, including endothelial function. There is a strong association between urinary albumin excretion and other cardiovascular risk factors (Fig. 78.2).¹ ESRD patients face an extraordinary risk for premature death, due largely to cardiovascular complications. However, the numbers of patients with non-dialysis-dependent CKD are much larger, and those with eGFR below 60 ml/min per 1.73 m² are much more likely to die than to develop ESRD,⁵ reflecting the burden of cardiovascular disease (CVD) in this high-risk population. The most effective strategy for reducing cardiovascular morbidity and mortality would be to target patients with mild renal impairment for prevention and treatment before severe CKD develops.

Unfortunately, CKD patients were often excluded from randomized controlled trials targeting CVD, or renal function was poorly described,⁶ possibly reducing acceptance of evidence-based therapies (validated in nonrenal patients) and fostering “therapeutic nihilism” in clinicians who treat CKD patients.

Like conventional atheromatous occlusive vascular disease, CKD is characterized by generalized vasculopathy with other characteristics, including left ventricular hypertrophy (LVH), vascular calcification, and vascular noncompliance. Numerous CVD risk factors are specific for CKD and operate in addition to conventional risk factors found in the general population.

EPIDEMIOLOGY

Prevalence of Cardiovascular Complications in Chronic Kidney Disease

Interpretation of epidemiologic studies of CVD in CKD is problematic because of the difficulty defining cause of death, but this difficulty is not limited to renal disease patients. Unexpected sudden death is most likely due to arrhythmia, but a subarachnoid hemorrhage, massive embolic stroke, or aortic dissection might be indistinguishable from a primary arrhythmic event without an autopsy. The real conundrum, however, is defining “coronary heart disease.” In the general population, sudden cardiac death is rightly considered a primary complication of coronary artery disease (CAD); evidence-based interventions

(e.g., statins) aimed at quelling the progression of atherosclerotic disease reduce the incidence of sudden death. However, in dialysis patients, sudden cardiac death is likely *not* to be a surrogate for coronary heart disease. Even using a history of angina to classify a patient as having coronary heart disease is problematic, as angina (due to supply-demand mismatch) can occur in patients with LVH and angiographically pristine coronary arteries. This probably relates to the increased myocardial fibrosis, diminished relative capillary density, and increased thickening of the intramyocardial vessel walls in uremia.

Of incident ESRD patients, 75% have LVH. Hypertension prevalence increases progressively with falling GFR; 75% to 85% of dialysis patients have hypertension (Fig. 78.3). With hypertension, anemia, vascular noncompliance, and volume overload contribute to LVH. Published data are sparse regarding left ventricular systolic function in incident ESRD patients after erythropoiesis-stimulating agents (ESAs) were introduced. Based on echocardiography, 85% to 90% of patients have preserved left ventricular systolic function, despite frequent congestive heart failure (CHF). As CHF is diagnosed in about 40% of incident ESRD patients within the first year,⁷ many volume overload episodes may be attributable to “diastolic dysfunction” or “circulatory congestion.” Whatever the mechanism, these hospitalizations are associated with high long-term mortality.⁸ Although occlusive CAD is common in CKD patients, acute myocardial infarction (AMI) accounts for only 15% of cardiac deaths; 66% of deaths in the United States Renal Data System (USRDS) database are attributable to arrhythmic mechanisms.¹

Cardiovascular Disease Is Present Before the Start of Renal Replacement Therapy

In elderly CKD patients at stage 2 or 3, traditional risk factors seem to be the major contributors to cardiovascular mortality. Atherosclerosis Risk in Communities (ARIC) data suggest that both traditional and novel risk factors are relevant at CKD stage 4,⁹ and studies of dialysis patients suggest that novel risk factors are far more prevalent than in the general population (Fig. 78.4). The Framingham predictive instrument does not accurately predict coronary events in CKD,¹⁰ another reflection of the necessary consideration of novel risk factors in predictive models for these patients.

Racial and International Differences in Cardiovascular Disease Prevalence

In the United States, after adjustment for demography and comorbid conditions, African American dialysis patients have better survival than do Caucasian patients. Differences in

Age-Standardized Rates of Death from Any Cause, Cardiovascular Events, and Hospitalizations

cardiovascular mortality among dialysis patients from the United States, Japan, and Europe are striking,¹¹ even after adjustment for standard risk factors and dialysis dose. Higher mortality rates in U.S. dialysis patients may be related to higher prevalence of sicker or diabetic patients or to differences in dialysis practice patterns; however, cultural habits, differences in diet, or genetic variations may also contribute.

Reverse Epidemiology

“Reverse epidemiology” is the seemingly paradoxical observation that the association between hypercholesterolemia, hypertension, obesity, and poor outcomes, including cardiovascular death, in the general population does not exist and may be reversed in the CKD population.¹² This concept is needlessly confusing and should be replaced by “confounded epidemiology.” Causality must not be confused with association. It is assumed (but open for debate) that wasted, inflamed patients account for poor survival and confounded epidemiology.

ETIOLOGY AND RISK FACTORS

Traditional Risk Factors

Age, Gender, and Smoking

The U.S. National Health and Nutrition Examination Survey (NHANES) shows the prevalence of cardiovascular risk factors and CVD prevalence in relation to age and CKD stage (Figs. 78.5 and 78.6). In the United States, the average age at initiation of renal replacement therapy is 63 years, when CVD is common. Female gender is associated with a 4% independent increased risk of mortality in incident dialysis patients.¹ Smoking is associated with an independent 52% increased risk of mortality in dialysis patients.¹³

Diabetes Mellitus

Diabetes accounted for 44% of incident U.S. ESRD patients in 2006⁷ and is the most common cause of ESRD in many countries. Diabetic patients starting renal replacement therapy exhibit a multifactor CVD risk factor profile, including dyslipidemia, hypertension, signs of inflammation, increased oxidative stress, and protein-energy wasting. Not surprisingly, diabetes at dialysis initiation is an independent risk factor for all-cause and CVD-related deaths, including after coronary revascularization or AMI; diabetic ESRD confers a 34% mortality risk after AMI compared with nondiabetic ESRD.

Hypertension

Hypertension is common and not always well treated in CKD patients. Of NHANES¹ participants with CKD stages 3 and 4, 80% were hypertensive (defined as blood pressure ≥130/≥80 mm Hg for CKD patients); 25% of these were unaware of being hypertensive, 7% were aware but untreated, 48% were treated but inadequately controlled (defined as blood pressure <130/<80 mm Hg), and only 20% were treated and adequately

Figure 78.1 Age-standardized rates of death from any cause (A), cardiovascular events (B), and hospitalization (C) according to estimated GFR among 1,120,295 ambulatory adults. A cardiovascular event was defined as hospitalization for coronary heart disease, heart failure, ischemic stroke, and peripheral arterial disease. Error bars represent 95% confidence intervals. The rate of events is listed above each bar. (Reprinted with permission from reference 2.)

controlled. Of participants with CKD stages 1 and 2, 63% were hypertensive; 40% of these were unaware, 13% were aware but untreated, 36% were treated but inadequately controlled, and only 11% were treated and adequately controlled. Low blood pressure is correlated with mortality in some dialysis patients (see [Reverse Epidemiology](#)). However, as in the general population, hypertension predicts mortality in CKD patients before or at dialysis initiation. Isolated systolic hypertension with increased pulse pressure is by far the most prevalent blood pressure anomaly in dialysis patients due to arterial medial sclerosis with secondary stiffening. Stiff vessels cause increased pulse wave velocity, resulting in increased systolic peak pressure by a prematurely reflected pulse wave, progressive left ventricular dysfunction, and finally CHF. This may subsequently result in decreased mean arterial and diastolic pressure and increased risk

for cardiovascular death. The relationship between blood pressure and mortality is U shaped; isolated systolic hypertension and increased pulse pressure probably indicate high long-term risk in dialysis patients, whereas low mean and diastolic blood pressures predict early mortality. The “invisible” hypertension danger relates to numerous CKD patients being “nondippers” (see Chapter 32). CKD patients frequently also experience sleep apnea, associated with nondipping, sympathetic nervous system activation, and cardiovascular risk.

Dyslipidemia

In CKD patients, the relationship between hypercholesterolemia, CVD, and mortality is weak because some major cardiovascular abnormalities, such as cardiomyopathy and arteriosclerosis, may be less dependent on dyslipidemia than on other factors. Paradoxically, low rather than high serum cholesterol level is associated with poor survival in hemodialysis patients,¹² confounded epidemiology related to protein energy wasting and inflammation. After adjustment for C-reactive protein levels, high cholesterol level predicted risk in relatively healthy ESRD patients without inflammation.¹⁴

Progressive CKD leads to changes in blood lipids associated with vascular disease, including decreased levels of apoA-containing lipoproteins and increased levels of apoB-containing lipoproteins (Fig. 78.7). Plasma triglyceride levels are elevated in most ESRD patients, whereas total serum cholesterol levels may be elevated, normal, or low, depending on nutritional status and presence of inflammation. High-density lipoprotein (HDL) cholesterol is typically reduced, and low-density lipoprotein (LDL), intermediate-density lipoprotein, and very low density lipoprotein cholesterol as well as lipoprotein(a) levels tend to be increased. Compared with long-term hemodialysis patients, peritoneal dialysis patients more often exhibit both hypercholesterolemia and hypertriglyceridemia. Both groups are characterized by low HDL and elevated oxidized LDL cholesterol levels; elevated lipoprotein(a) levels are associated with increased CVD mortality.

Insulin Resistance and Atherosclerosis

In the general population, impaired insulin-stimulated glucose disposal in muscle is often part of a metabolic syndrome that

Figure 78.4 Risk factors. Schematic overview of traditional (i.e., Framingham) risk factors (green), “novel” risk factors (orange), and more or less “uremia-specific” risk factors (blue).

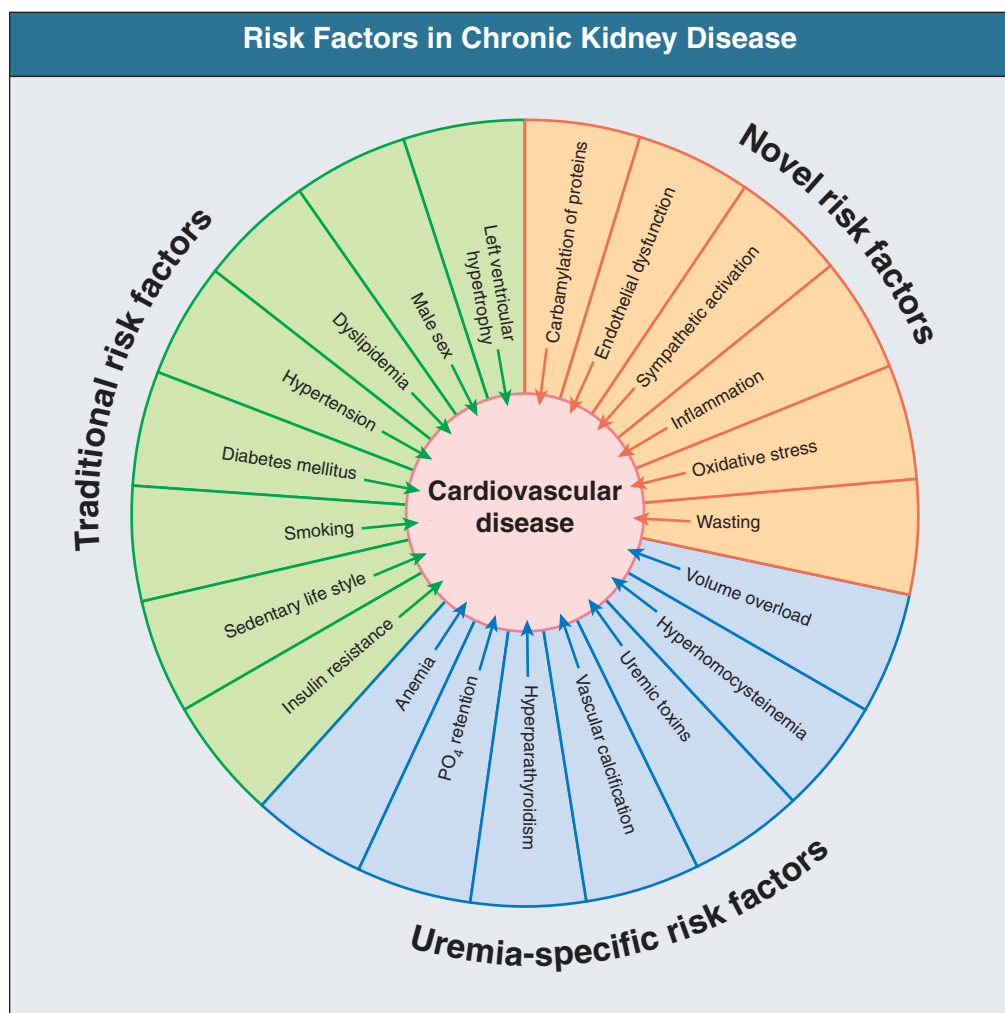

Figure 78.5 Prevalence of comorbidities in the NHANES population, by CKD stage. DM, diabetes mellitus; HTN, hypertension; CVD, cardiovascular disease. (U.S. Renal Data System. *USRDS 2008 Annual Data Report: Atlas of Chronic Kidney Disease and End-Stage Renal Disease in the United States*. Bethesda, Md, National Institutes of Health, National Institute of Diabetes and Digestive and Kidney Diseases, 2008.)

includes dyslipidemia, hypertension, endothelial dysfunction, and sympathetic overactivity. Many of these abnormalities are present in CKD. Although insulin resistance was found to be an independent predictor of cardiovascular mortality in dialysis patients,¹⁵ its contribution to CKD patient mortality is uncertain.

Nontraditional and Uremia-Specific Risk Factors

Several large prospective population studies have shown that even mild CKD is an independent risk factor for CVD, independent of hypertension, diabetes, and albuminuria (Fig. 78.8). Because about 10% of low-risk and 30% of high-risk CVD populations have mild CKD, it is now regarded as an independent cardiovascular risk factor similar in magnitude to diabetes and hypertension. The uremic milieu may affect both quality and quantity of the atherosclerotic plaques. Coronary lesions in uremic patients, compared with nonrenal controls, are characterized by increased media thickness, infiltration, and activation of macrophages and marked calcification.¹⁶ The mechanism by

which a uremic milieu may accelerate atherosclerosis is not well established, but prevalence and magnitude of several nontraditional risk factors, such as oxidative stress, inflammation, vascular calcification, and advanced glycation end products (AGEs), increase as renal function deteriorates. Other uremic retention solutes, such as asymmetric dimethylarginine (ADMA), homocysteine, guanidine, indoxyl sulfate, and *p*-cresol, which accumulate in CKD, may have proatherogenic properties.¹⁷ Finally, the kidneys produce substances that may inhibit CVD and atherogenesis, for example, reninase, a soluble monoamine oxidase that regulates cardiac function and blood pressure.¹⁸

Oxidative Stress

Oxidative stress may be implicated in the pathogenesis of atherosclerosis and the increased risk of atherosclerotic cardiovascular events and in other CKD complications, such as protein-energy wasting and anemia.¹⁹ Increased production of reactive oxygen species in the vascular wall is a characteristic feature of atherosclerosis.¹⁹ Early CKD (stage 3), and in particular uremia, is a pro-oxidant state resulting from reduced antioxidant systems (vitamin C and selenium deficiency, reduced intracellular vitamin E levels, reduced glutathione system activity) and increased pro-oxidant activity associated with advanced age, diabetes, chronic inflammation, retained uremic solutes, and bioincompatibility of dialysis membranes and solutions.¹⁹ Four oxidative stress pathways can be hypothesized in CKD: carbonyl stress, nitrosative stress, chlorinated stress, and classical oxidative stress (Fig. 78.9).

Inflammation

Most dialysis patients are in a state of chronic inflammation; inflammatory biomarkers such as C-reactive protein, interleukin-6, fibrinogen, and white blood cell count are robust and independent predictors of mortality in CKD patients. Hypoalbuminemia, a biochemical factor strongly associated with systemic inflammation, is another strong outcome predictor in CKD. Whereas both dialysis-related (dialysis system bioincompatibility) and non-dialysis-related (infection, comorbidity, genetic factors, diet, renal function loss) factors may contribute to chronic inflammation, its primary causes are not always evident. As in the general population, it is unclear in CKD whether the acute-phase response only reflects established atherosclerotic disease or is involved in the initiation and progression of atherosclerosis. Some inflammatory biomarkers, such as interleukin-6, pentraxin 3, and tumor necrosis factor α , may have

Figure 78.6 Prevalence of CVD in the NHANES population, by age and CKD stage. (U.S. Renal Data System. proatherogenic properties, such as promoting vascular calcification, oxidative stress, and endothelial dysfunction (Fig. 78.10). Evidence also suggests associations between inflammation and development of albuminuria. The link between septicemia and subsequent increased risk of death and cardiovascular events, including AMI, in observational studies further supports inflammation as a trigger for cardiovascular events.²⁰

Endothelial Dysfunction

As in other clinical disorders characterized by a high burden of vascular disease, endothelial dysfunction (as evaluated by

impaired endothelium-dependent vasodilation) is a prominent feature of CKD. Reasons include inflammation, ADMA retention, oxidative stress, hyperhomocysteinemia, dyslipidemia, hyperglycemia, and hypertension. Surrogate markers of endothelial dysfunction, such as ADMA, pentraxin 3, and adhesion molecules, independently predict death.²¹ Detached circulating endothelial cells serve as potential markers of endothelial damage in renal and nonrenal patients and have prognostic value in hemodialysis patients.²¹ Normally, in response to ischemic insult and cytokine stimulation, endothelial progenitor cells are mobilized from the bone marrow to act as “repair” cells for the endothelial injury. As CKD patients seem to have reduced numbers or functional impairment of endothelial progenitor cells due to inflammation or uremic toxins, they seem predisposed to endothelial dysfunction. Recent data support an independent association between circulating fibroblast growth factor 23 (FGF-23) and endothelial dysfunction,²² and future studies are required to validate whether FGF-23 is a modifiable cardiovascular risk factor.

Anemia

Anemia is a major cause of LVH and left ventricular dilation in CKD. Although partial correction of anemia with ESAs results in LVH regression, current information does not suggest any cardiovascular outcome benefit of normalized hemoglobin (see Chapter 79).

Secondary Hyperparathyroidism and Mineral Metabolism

Disturbances of calcium and phosphate metabolism starting as early as CKD stages 3 and 4 might accelerate calcifying atherosclerosis and arteriosclerosis. In registry data, a strong independent mortality risk is predicted by hyperphosphatemia, an intermediate risk by elevated serum calcium levels, and a weak but significant risk by high or low serum intact parathyroid hormone levels. The overall mortality risk prediction

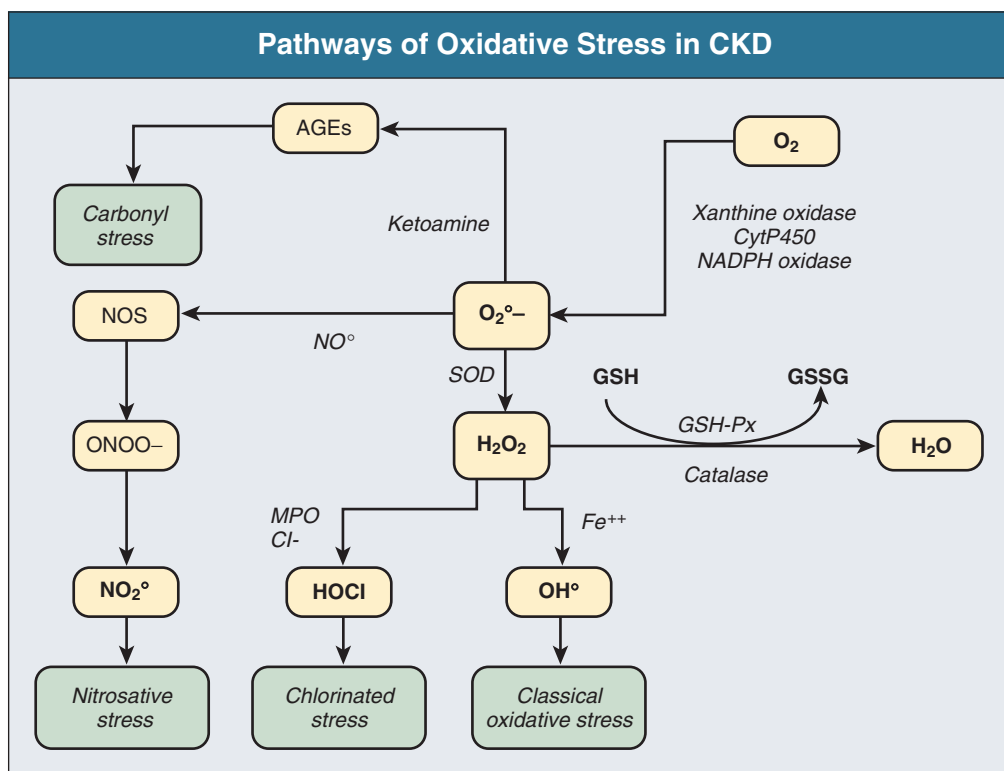

Figure 78.8 Relative risk for mortality (RR mortality) versus GFR. The majority of studies used the Cockcroft and Gault formulae to estimate clearance (triangles). Studies using the MDRD formula are indicated by the squares and unadjusted studies by the crosses.

attributable to mineral metabolism disorders is estimated to be about 17% in hemodialysis patients.²³

Cardiovascular Calcification

Cardiovascular calcification may affect the arterial media, atherosclerotic plaques, myocardium, and heart valves. Medial calcification causes arterial stiffness and, consequently, increased pulse pressure. The pathophysiologic role of plaque calcification is less clear because soft plaques are assumed to rupture and to cause AMI; atherosclerotic calcification is a potent risk marker of cardiovascular events, but its utility as a risk marker for clinical management of CKD patients remains controversial. Valvular calcification mostly affects the aortic and mitral (annulus) valves in dialysis patients and contributes to progressive stenosis and associated morbidity; mitral annular calcification is associated with increased mortality.²⁴ In dialysis patients, extensive vascular, especially coronary artery, calcification can be observed at young ages. Calcium and phosphate metabolism disturbance is an important factor in cardiovascular calcification in ESRD. Serum phosphate level of 5.0 mg/dl or higher (≥ 1.62 mmol/l) is associated with increased risk for valvular heart surgery in hemodialysis patients.²⁵ Calciphylaxis (calcific uremic arteriopathy), characterized by severe calcifications of cutaneous arterioles and tissue necrosis, is discussed in Chapter 84.

Vascular calcification is not derived only from passive calcium and phosphate precipitation. Rather, it is a highly regulated active process involving differentiation of vascular smooth muscle cells toward osteoblasts induced by phosphate, calcium, and other factors, such as calcitriol and pro-inflammatory. One way by which chronic inflammation promotes vascular calcification may involve downregulation of fetuin-A, the most potent circulating inhibitor of extraosseous calcification. In cross-sectional studies, dialysis patients with low serum fetuin-A levels showed significantly poorer survival than did those with normal values.²⁶ Apart from fetuin-A, other inhibitors probably counteract unwanted calcification. Leptin, matrix GLA protein, pyrophosphates, bone morphogenic proteins (e.g., BMP-2 and BMP-7), and osteoprotegerin may be related to accelerated vascular calcification in ESRD.

Advanced Glycation End Products

AGEs accumulate in CKD patients as a result of nonenzymatic glycation, oxidative stress, and diminished clearance of AGE precursors. Stable AGE residues of long-lived proteins are biomarkers of cumulative metabolic, inflammatory, and oxidative stress; carbonyl stress is speculated to contribute to tissue aging and long-term CKD complications. Whether AGE inhibition may be a useful intervention to reduce cardiovascular events and mortality is unknown.

Hyperhomocysteinemia

Homocysteine is a nonprotein sulfur-containing amino acid that may be protein bound (70% to 80%), free oxidized (20% to 30%), or free reduced (~1%). Hyperhomocysteinemia prevalence in CKD patients is more than 90%. In contrast to the well-documented association between total homocysteine and vascular disease in the general population, the association between total homocysteine and CVD is not consistent in CKD. The strong associations between total homocysteine and hypoalbuminemia, protein-energy wasting, and inflammation are likely to explain the observed paradoxical association between outcome and total homocysteine levels. As total homocysteine exists mainly in a protein-bound form, it has a strong positive correlation with serum albumin, and this association may explain why some studies demonstrate better outcome in CKD patients with higher total homocysteine levels.

Dialysis Modality

Reports from dialysis registries are inconsistent regarding whether hemodialysis or peritoneal dialysis is associated with better outcomes.²⁷ Valid mortality comparisons between modalities would require stratification of patients according to underlying ESRD cause, age, and level of baseline comorbidity.²⁷ Such data are currently not available.

CLINICAL MANIFESTATIONS AND NATURAL HISTORY

Chest Pain, Coronary Artery Disease, and Acute Myocardial Infarction

AMI in dialysis patients is associated with poor long-term survival. The unadjusted 73% 2-year mortality rate (Fig. 78.11) has

changed minimally during 25 years, despite dramatic improvements in AMI outcomes in the general population. This heightened mortality is not restricted to ESRD patients, as in-hospital deaths increase with decreasing GFR (Fig. 78.12).²⁹ Furthermore, the likelihood of prescribing evidence-based therapies including aspirin and β -blockers in CKD patients is diminished,^{29,30} although these therapies decrease mortality in such patients.

Prior speculations have attributed this poor outcome to underrecognition due to “atypical” presentations³⁰ and undertreatment (therapeutic nihilism).^{30,31} The collaborative USRDS/National Registry of Myocardial Infarction study³¹ of dialysis patients hospitalized for AMI found a lower diagnostic suspicion of acute coronary syndromes; 45% of dialysis patients were diagnosed incorrectly versus 21% of nondialysis patients. This partly reflects a lower prevalence of chest pain, experienced by 44% of dialysis patients and 68% of nondialysis patients. Surprisingly, only 19% of dialysis patients (versus 36% of nondialysis patients) had ST-segment elevation. After other clinical exclusions, only 10% of dialysis patients, versus 25% of nondialysis patients, were eligible for acute coronary reperfusion. Of those who were eligible, 47% of dialysis and 75% of nondialysis patients actually received reperfusion. In-hospital death was 21% for dialysis and 12% for nondialysis patients. In-hospital cardiac arrest occurred twice as frequently in dialysis as in nondialysis patients (11% versus 5%).

Peripheral Arterial Disease

Risk for peripheral arterial disease is highest for dialysis patients with diabetes or preexisting atherosclerosis. In hemodialysis patients, peripheral arterial disease is also associated with time on dialysis, hypoalbuminemia, low parathyroid hormone levels, and low predialysis diastolic blood pressure. Vascular medial calcification of large peripheral arteries may not indicate presence of occlusive disease, and peripheral gangrene is often caused by diabetic or other small-vessel disease or rarely by calcific uremic arteriolopathy (see Chapter 84). Peripheral arterial disease is associated with increased mortality; outcomes after revascularization are worse than for the general population,³² in part reflecting advanced vasculopathy.

Cerebrovascular Disease

Cognitive impairment is underrecognized in dialysis patients; in one study, more than a third of patients showed severe cognitive impairment and only 15% normal cognition.³³ Cognitive impairment prevalence increases approximately 10% per 10 ml/min per 1.73 m² of eGFR less than 60 ml/min per 1.73 m².³⁴ Microalbuminuria and stage 3 CKD increased stroke risk 1.5- to 2-fold in a multivariate model.^{35,36} Incident dialysis patients have a six-fold age-adjusted relative risk of stroke compared with the general population; the unadjusted rate for stroke hospitalization for dialysis patients was 48 per 1000 patient-years, and 10.6% were attributed to hemorrhagic stroke.³⁷ Stroke accounts for 4% of ESRD deaths in the USRDS registry (see Chapter 82 for more details).¹

Left Ventricular Remodeling and Hypertrophy

LVH is a potent predictor of mortality in ESRD patients. LVH is associated with a 60% increased risk of sudden death and a more than twofold increased risk of stroke.³⁸ LVH occurs early

Figure 78.11 Estimated mortality of dialysis patients after acute myocardial infarction. (Reprinted with permission from reference 28. © 2003 American Society of Nephrology.)

Figure 78.12 In-hospital mortality as a function of creatinine clearance. (Reprinted with permission from reference 29. © 2003 American Society of Nephrology.)

in progressive CKD, probably because of high hypertension prevalence, including frequent nocturnal hypertension. Pressure overload, caused by hypertension and arterial stiffness, results in concentric hypertrophy. Volume overload is manifested as “eccentric” hypertrophy. Left ventricular dilation strongly predicts poor outcome. It may be an end result of severe LVH, diffuse ischemic damage, or recurrent volume overload; high-output arteriovenous fistula may contribute. Diastolic dysfunction is strongly associated with LVH and with increased risk for intradialytic hypotension because relatively small reductions in left atrial filling have significant effects on cardiac output in these stiff, hypertrophied preload-sensitive hearts, together with Bezold-Jarisch reflex activation through stimulation of left ventricular posterior wall stretch receptors in “underfilled,” hypercontractile, hypertrophied ventricles.

Extracellular Volume Overload

Extracellular volume overload resulting from loss of sodium excretory capacity is the major cause of hypertension in dialysis patients. Whether prevention of recurrent hypervolemia reduces cardiovascular morbidity and mortality remains unproved. If adjusted for comorbidity and advanced age, a strong, incremental risk of all-cause and cardiovascular mortality is associated with interdialytic weight gains.³⁹ Recurrent hypervolemia may result in LVH and left ventricular dilation, peripheral or pulmonary edema, raised jugular vein pulse, or a third heart sound, or it may be largely asymptomatic. Tolerance of large ultrafiltration volumes may indicate that the dry weight target (see Chapter 90) has not been reached. Reaching an optimal dry weight, however, does not necessarily lead to immediate blood pressure correction; a lag phase of some weeks can precede improvement.

Pericarditis

Pericarditis from untreated uremia is rare today. The more common dialysis-associated pericarditis may be related to

intercurrent illnesses (including viral infections), fistula recirculation, or underlying diseases such as systemic lupus erythematosus, but the exact pathogenesis remains obscure. Fever with pericardial pain or a rub on heart auscultation, unexplained cardiomegaly on chest films, or hemodynamic instability should prompt echocardiography. An effusion causing overt hemodynamic compromise (i.e., pericardial tamponade) or large pericardial effusions judged unlikely to resolve with conservative measures require echocardiographically or computed tomography (CT)-guided pericardiocentesis or surgical drainage. Intensive dialysis is indicated for “true” uremic pericarditis; the optimal treatment of “dialysis-associated” pericarditis is much less clear in patients without hemodynamic compromise.⁴⁰ Aggressive anticoagulation should be avoided because of increased (but not well defined) risk for development of hemorrhagic pericarditis and pericardial tamponade.

Autonomic Dysfunction

CKD involves decreased baroreflex sensitivity, which has been linked to increased risk of sudden death.⁴¹ Increased sympathetic nerve activity, including secondary to sleep apnea, is a common alteration in CKD patients and associated with adverse outcome.⁴²

Valvular Disease

The calcific aortic stenosis progression rate is approximately three times faster in dialysis patients than in the general population (0.23 versus 0.05 to 0.1 cm² per year).⁴³ Annual Doppler echocardiographic follow-up is recommended for asymptomatic dialysis patients who are suitable candidates for cardiac surgery with aortic valve area of 1.0 cm² or less.⁴⁴ A USRDS study of 5825 dialysis patients undergoing valvular replacement surgery found no difference in survival for patients receiving tissue versus nontissue valves.⁴⁵ The overall mortality is high, with in-hospital mortality about 20% and 2-year survival 40%.

Infective Endocarditis

Estimated incidence of infective endocarditis in U.S. dialysis patients is 267 cases per 100,000 patient-years.⁴⁶ Vascular access, including temporary and semipermanent catheters, is an important source of infection; heightened risk of bacteremia related to hemodialysis therapy is likely an important aspect of endocarditis risk. Dialysis patients with bacterial endocarditis have poor long-term survival. In-hospital mortality was 24% and 1-year survival only 38% for patients hospitalized in 1997-2000.⁴⁷

Sudden Cardiac Arrest

In the USRDS database, 60% to 65% of cardiac deaths (25% to 27% of all-cause mortality) in dialysis patients are attributable to arrhythmic mechanisms.¹ Although obstructive CAD is likely to be an important cause of sudden cardiac death, it is probably not the major one (unlike in the general population). The 4D study found that statin therapy had no impact on sudden death,⁴⁸ and a USRDS study found that coronary revascularization does not nullify the risk of sudden cardiac death for dialysis patients.⁴⁹ Sudden cardiac death is independently associated with inflammatory biomarkers.⁵⁰ Myocardial fatty acid imaging might identify patients at risk for sudden death.⁵¹ Factors probably contributing to the special vulnerability of ESRD patients to sudden cardiac arrest include LVH; rapid electrolyte shifts and hyperkalemia in hemodialysis; autonomic dysfunction and sympathetic overactivity, including sleep apnea; and abnormalities in myocardial ultrastructure and function, including endothelial dysfunction, interstitial fibrosis, decreased perfusion reserve, and diminished ischemia tolerance.^{30,52} Sudden death may be attributable to the rapid electrolyte shifts that occur in hemodialysis, particularly because risk of death increases by 50% on the day after dialysis⁵³; however, although the rate of cardiac arrest is 50% higher for hemodialysis than for peritoneal dialysis patients 3 months after initiation of renal replacement therapy, it is higher for peritoneal dialysis patients at 3 years.⁵⁴ One study of cardiac arrests occurring in hemodialysis centers found that the predominant rhythm was ventricular fibrillation (66%), followed by pulseless electrical activity (23%) and asystole (10%).⁵⁵

Non-dialysis-dependent CKD is also associated with increased risk of sudden cardiac death. In women with coronary heart disease in the Heart and Estrogen Replacement Study, eGFR below 40 ml/min per 1.73 m² was associated with a 2.3-fold increased risk of sudden cardiac death. Despite a graded, incremental risk of arrhythmic death and impaired renal function, the overall magnitude of risk in stage 3 CKD patients is small compared with dialysis patients.

The role that implantable cardioverter-defibrillators (ICDs) may play in reducing mortality in CKD patients is controversial, particularly regarding “primary prevention” of sudden death in patients with left ventricular ejection fraction of 35% or lower (comparable general population patients receive ICDs under current U.S. implant guidelines). CKD may attenuate the survival advantage of ICDs for primary prevention of sudden cardiac death,^{56,57} but older age and medical comorbidity should not routinely exclude patients from receiving ICDs. Nevertheless, ICDs were underused in dialysis patients who survived cardiac arrest in 1996-2001, and ICD implantation was associated with a 42% reduction in long-term mortality.⁵⁸

The reported rate of cardiac arrest in hemodialysis centers is 3.8 to 7.1 events per 100,000 dialysis sessions.^{55,59,60} On-site

defibrillation capability (preferably with automatic external defibrillators) was recommended as a U.S. practice guideline in 2005,⁴⁴ but this has been challenged by Lehrich and colleagues.⁵⁹

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Key issues in the diagnosis of CVD are underrecognition of symptoms, underuse of appropriate diagnostic investigations, and interpretation of those investigations.

Blood Pressure Measurements

Outcome prediction by ambulatory blood pressure monitoring is not necessarily better than by office blood pressure measurements. However, ambulatory monitoring is useful to identify high-risk nondippers and inverted dippers, allowing consequent treatment adjustments.

Electrocardiography and Echocardiography

KDOQI clinical practice guidelines for CVD in dialysis patients recommend a baseline electrocardiogram at dialysis initiation and at annual intervals.⁴⁴ In the 4D trial,³⁸ patients presenting without sinus rhythm (11% of the cohort) were 89% more likely to die (based on multivariate analysis) and 164% more likely to sustain a stroke. In the Cardiovascular Health Study, CKD patients (eGFR <60 ml/min per 1.73 m²) with increased QRS duration had 15% greater risk of incident CHF, 13% greater risk of incident coronary heart disease, and 17% greater risk of mortality per 10-millisecond increase; prolongation of the QT interval was also independently associated with adverse outcome.⁶¹

KDOQI guidelines recommend routine echocardiograms in all dialysis patients after they achieve “dry weight” targets, preferably 1 to 3 months after dialysis initiation on an interdialytic day for hemodialysis patients and at 3-year intervals thereafter.⁴⁴ The rationale for this guideline is that diminished left ventricular systolic function is independently associated with incident CHF, recurrent CHF, incident ischemic heart disease, and increased mortality,⁴⁴ and it is not accurately diagnosed by history, physical examination, or chest radiography. Detection of unsuspected cardiomyopathy is also important, given that carvedilol therapy in such patients improved left ventricular systolic function, decreased hospitalization, and reduced mortality.⁶² As in the general population, CKD patients with a left ventricular ejection fraction below 40% should be evaluated for CAD (exceptions are pediatric or young adult patients with nondiabetic renal failure and other patients known to be at low risk for CAD).

Stress Tests and Screening Renal Transplant Candidates

ESRD patients are poorly suited for conventional exercise stress electrocardiography because of limited exercise tolerance and frequent resting electrocardiographic abnormalities. Accuracies of pharmacologic stress echocardiographic and nuclear scintigraphic techniques are remarkably variable over the world; they clearly are operator dependent, and the approach of individual sites to cardiac screening should rely on institutional expertise. Moreover, prediction of the likelihood of future events may differ considerably from prediction of coronary anatomy. In severe CKD, dobutamine stress echocardiography is an independent predictor of long-term mortality.⁶³ Sensitivities and

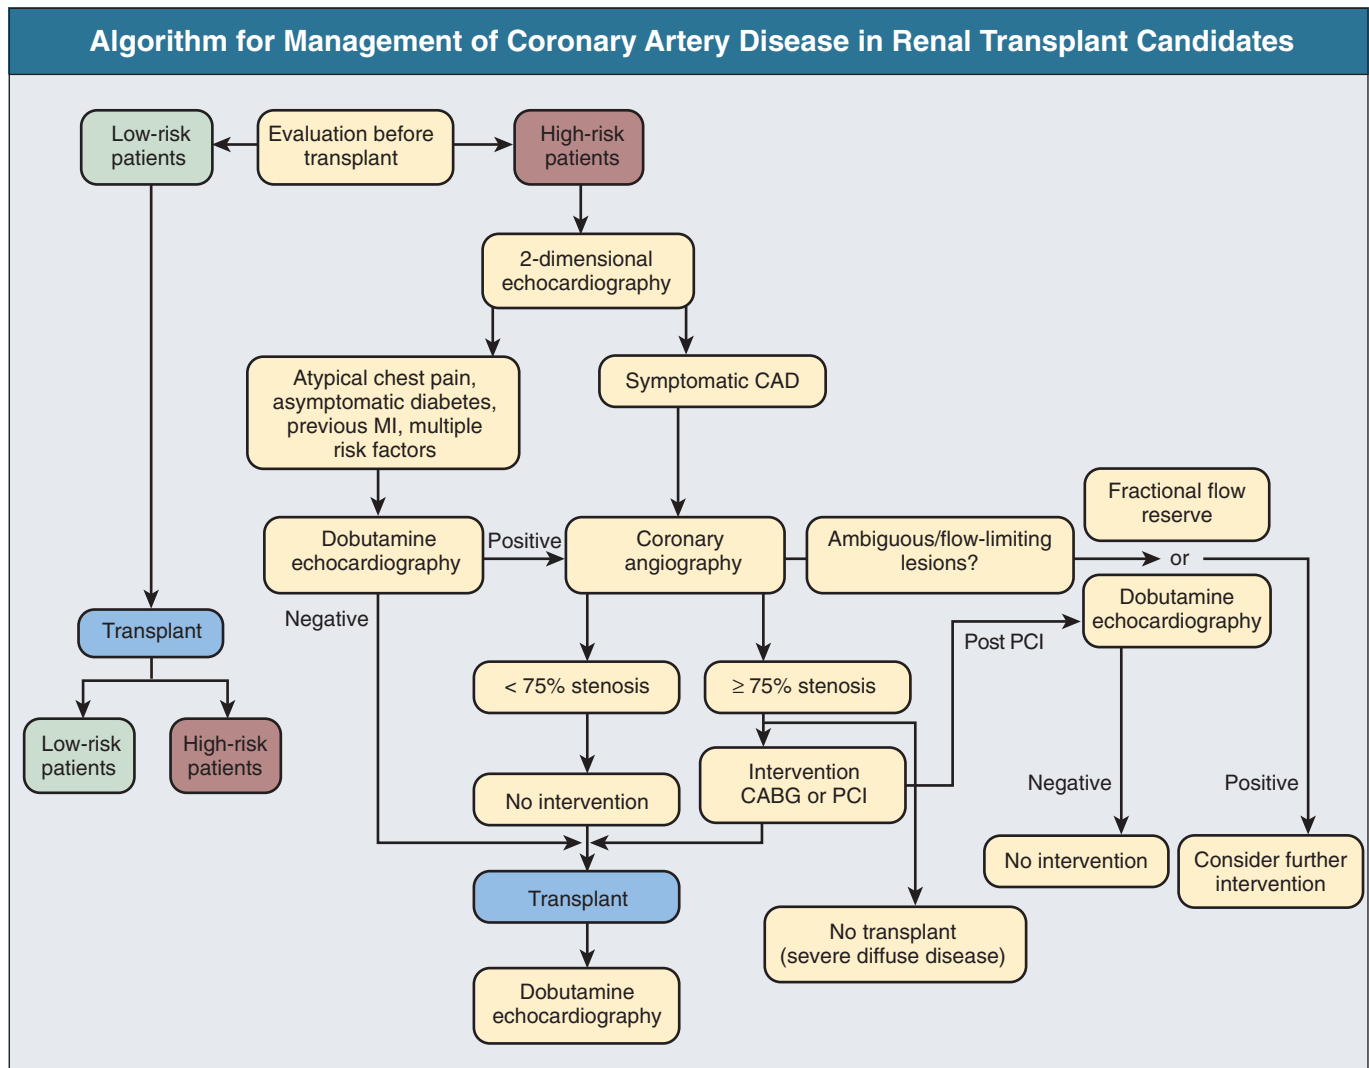

Figure 78.13 Algorithm for management of coronary artery disease in renal transplant candidates. CABG, coronary artery bypass graft surgery; CAD, coronary artery disease; MI, myocardial infarction; PCI, percutaneous coronary intervention. (Modified from reference 64.)

specificities for detection of CAD in renal transplant candidates have been reported to range from 44%⁶⁵ to 75%⁶⁶ and up to 90%.⁶⁷ A meta-analysis⁶⁸ concluded that presence of inducible myocardial ischemia by any stress imaging test is independently predictive of increased AMI risk and cardiac death, whereas a fixed or resting defect or abnormality is predictive of cardiac death but not AMI.

The major problem with “screening” is use of test results for clinical management. The evidence base for “prophylactic” revascularization of asymptomatic renal transplant candidates (or any other patient group) is weak³⁰; optimal medical therapy (which should constitute the treatment strategy for all patients) may potentially attenuate the putative benefit of prophylactic coronary revascularization. In our institution, we use the algorithm presented in Figure 78.13 for screening and management of CAD in renal transplant candidates. All patients undergo resting echocardiography, and high-risk patients (most of our ESRD patients) undergo stress echocardiography. For patients subsequently found to have angiographically indeterminate lesions, measurement of fractional flow reserve is used to make decisions about revascularization.⁶⁹

Coronary Angiography

Coronary angiography, the gold standard in evaluating CAD in CKD, should be considered in stable ESRD patients with evidence for inducible myocardial ischemia, unstable patients with acute coronary syndrome (performed urgently for ST-segment elevation myocardial infarction), and patients with a left ventricular ejection fraction below 40%. Some reports suggest a predilection for more proximal CAD in CKD patients, which may predict worse outcome.^{70,71}

In CKD and ESRD with residual renal function, fear of contrast nephropathy may restrain use of coronary angiography (see Chapter 69 for preventive measures). Echocardiography should be performed before any nonemergent coronary angiography in CKD patients to diagnose clinically unsuspected valvular disease or cardiomyopathy, to gauge preprocedure volume status, and to assess left ventricular function (to avoid excessive exposure to radiocontrast media through unwarranted ventriculography).

Noninvasive coronary CT angiography may be problematic in dialysis patients because of medial calcification interfering with angiographic interpretation. Another problem may be the

requirement for a large-bore intravenous line for rapid injection of radiocontrast media. Noninvasive gadolinium-based magnetic resonance angiographic imaging in patients with severe CKD is no longer recommended because of concerns about nephrogenic fibrosing dermopathy; the value of imaging without contrast media is unknown.

Imaging of Vascular Calcification

Vascular calcification can be visualized by conventional x-ray techniques and by multislice spiral CT or electron-beam CT. Valvular and large artery calcification can be visualized by ultrasound techniques. Detection of any cardiovascular calcification predicts worse outcome in dialysis patients. The value of routine imaging of vascular calcifications in CKD patients is currently not defined. The diagnostic significance of coronary artery calcification in dialysis patients as a surrogate for CAD severity has been questioned.⁷²

Biomarkers

Plasma brain natriuretic peptides (BNP and NT-proBNP), cardiac troponins (cTnT, cTnI), and high-sensitivity C-reactive protein are prognostic risk markers in the evaluation of heart disease in ESRD.⁷³⁻⁷⁵ BNP reflects cardiac filling pressures (not limited to the left side of the heart), troponins reflect myocardial cell death (but not necessarily ischemia, as apoptosis or nonischemic cardiomyopathy might cause elevated plasma troponin levels), and high-sensitivity C-reactive protein is an inflammatory marker. Elevation of cTnT occurs in pediatric CKD patients and is associated with cardiac dysfunction.⁷⁶ Elevation of plasma troponin levels in ESRD patients is *not* a “false positive”; the origin is myocardial, but the interpretation is incorrect if it is uncritically attributed to myocardial ischemia. The cardiac biomarker-based diagnosis of acute coronary syndrome requires a time-appropriate rise and fall of the biomarker. The most cost-effective combination of biomarkers for risk stratification in dialysis patients might be cTnT and high-sensitivity C-reactive protein, but this is controversial. In asymptomatic non-dialysis-dependent CKD patients, plasma cTnT and cTnI were elevated in at least a third of patients, but only cTnT was predictive of death.⁷⁷ In CKD, NT-proBNP and BNP are equivalent predictors of decompensated heart failure, but NT-proBNP is a better predictor of survival.⁷⁸ Figure 78.14 graphically displays the relationship of cTnT and cTnI levels in asymptomatic dialysis patients and long-term survival. On the basis of these data, the U.S. Food and Drug Administration approved the measurement of cTnT in dialysis patients for the indication of risk stratification (mortality prediction) in 2004⁴⁴; however, utility of the information in clinical practice remains unclear.

TREATMENT AND PREVENTION OF CARDIOVASCULAR DISEASE

Risk Factor Reduction

Smoking

It is clearly imperative to strongly encourage smoking cessation at any CKD stage.

Weight and Diet

Lifestyle changes, including balanced diets with regard to saturated fat and carbohydrates (in diabetic patients), probably

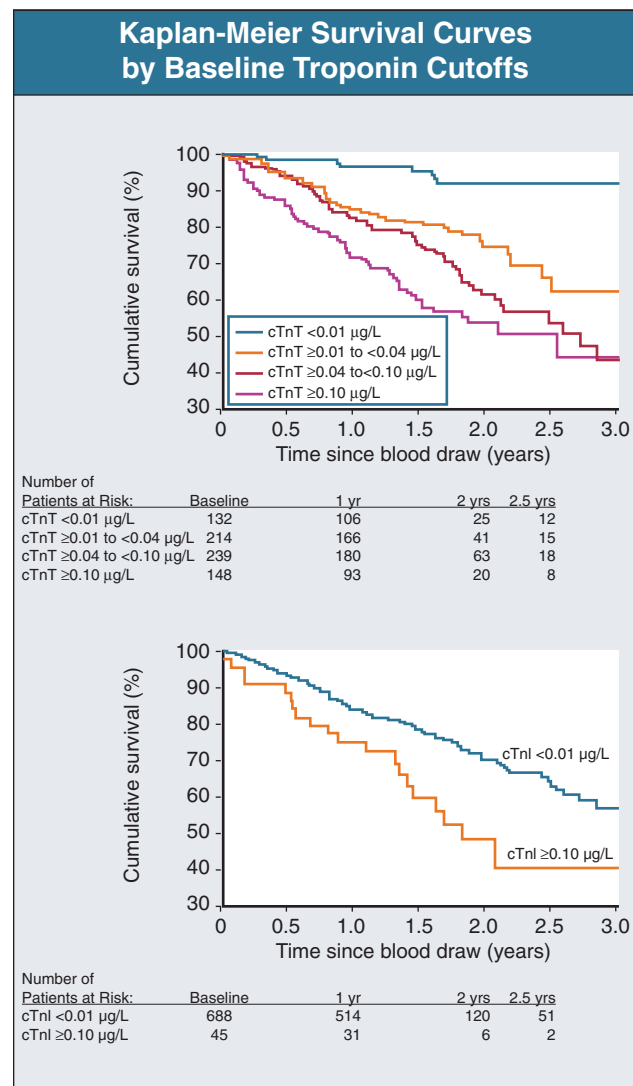

Figure 78.14 Kaplan-Meier survival curves by baseline troponin cutoffs. cTnT, cardiac troponin T; cTnI, cardiac troponin I. (From reference 73.)

reduce cardiovascular morbidity and should be encouraged. However, in all CKD stages, protein energy wasting must be avoided; especially in dialysis patients, increased body mass index has been associated with improved outcomes in the United States,⁷⁹ possibly reflecting confounded epidemiology. Correction of obesity should be encouraged. Low-salt diet and phosphate restriction are discussed in Chapter 83.

Hypertension and Coronary Artery Disease

Arterial hypertension is undertreated in many CKD and ESRD patients, and despite controversial data about the risk prediction by diastolic and systolic blood pressure in dialysis patients, anti-hypertensive treatment is associated with improved survival. Blood pressure targets for CKD patients, in particular those with diabetes or proteinuria exceeding 1 g/day, are discussed in Chapter 76. Hallmarks of therapy are volume control (see Chapter 90) and prevention of salt overload, particularly through dietary sodium restriction. Longer or more frequent hemodialysis sessions may be beneficial in controlling hypertension. Because of their parallel cardioprotective effects, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor

blockers (ARBs), and vasodilating β -blockers (e.g., carvedilol) are the first-line drugs to treat CKD- and ESRD-related hypertension. Calcium channel blockers and most other antihypertensive drugs, including centrally acting sympathetic inhibitors, are useful when administered complementarily. Pure vasodilators (e.g., minoxidil) must be used with caution because they may increase volume overload or occasionally cause pericardial effusions.

CAD and CAD-related events should be treated with the same medications and active interventions indicated in the non-renal population in the absence of convincing CKD-specific data to the contrary. Medical treatment includes use of antiplatelet agents, ACE inhibitors, ARBs, β -blockers, nitroglycerin, and statins. There is no rationale for a less aggressive therapeutic approach for CKD and ESRD patients than for the nonrenal population.

Diabetes Mellitus

Optimal glycemic control, reaching blood pressure target levels, and lipid monitoring (with subsequent dyslipidemia treatment) are all crucial in managing diabetic CKD patients. CAD and other CVD should be treated aggressively in this high-risk group.

Dyslipidemia

If CKD (like diabetes) is considered a “CHD equivalent,” CKD patients should be treated to secondary prevention LDL cholesterol target guidelines (<100 mg/dl or 2.6 mmol/l). However, this contention is currently unsupported by clinical trials targeting CKD patients, notably the 4D trial of atorvastatin in type 2 diabetic dialysis patients.⁴⁸ The AURORA study⁸⁰ found that rosuvastatin failed to reduce time to cardiovascular death, nonfatal AMI, or stroke in hemodialysis patients. *Post hoc* subgroup analyses in the Heart Protection Study,⁸¹ Cholesterol and Recurring Events study,⁸² and Treating to New Targets study,⁸³ together with a meta-analysis,⁸⁴ provide inferential support for the role of statins in improving outcomes in CKD stage 1 or 2 patients. The Study of Heart and Renal Protection (SHARP) testing the effect of lipid lowering in CKD stage 3 and stage 4 patients is ongoing. Statin treatment is recommended in CKD patients older than 20 years with goals of LDL cholesterol levels above 130 mg/dl (3.4 mmol/l) or above 100 mg/dl (2.6 mmol/l) for secondary prevention; however, the negative 4D and AURORA results do not support this guideline in dialysis patients.

Volume

In predialysis CKD, sodium restriction and diuretics are important to counteract fluid retention. In ESRD, longer and more frequent hemodialysis sessions may permit more effective volume control. In the hemodialysis center in Tassin, France, more than 90% of patients were normotensive with 8 hours of dialysis three times per week, with dietary salt restriction and no antihypertensive drugs. Episodes of dialysis-related hypotension should prompt re-evaluation of dry weight, antihypertensive treatment, and exclusion of pericardial effusions, valvular disease, cardiomyopathy, or silent myocardial ischemia (see Chapter 91).

Anemia

Partial correction of severe anemia with ESAs results in regression of LVH. Treatment of severe anemia is also associated with fewer ischemic symptoms in CAD patients. However, evidence for reduction of cardiovascular mortality by ESAs is based on observational data only. To date, a randomized controlled trial

in hemodialysis patients,⁸⁵ and the CHOIR⁸⁶ and CREATE⁸⁷ studies in CKD patients, have shown no benefit of normalized anemia (>13.5 g/dl) on mortality as a primary endpoint (see Chapter 79). Until results from the ongoing TREAT study on the effects of darbepoetin on outcome are available, anemia correction in CKD patients to a hemoglobin interval between 11 and 12 g/dl appears logical.

Inflammation

Anti-inflammatory treatment strategies, such as statins and aspirin, have beneficial effects on cardiovascular mortality in the general population, but few data are available to support that such therapies decrease inflammation in CKD patients. Recent data from the 4D study⁴⁸ show that whereas C-reactive protein baseline levels were not significantly different between treated and placebo groups and remained stable at 6 months with atorvastatin, they increased significantly in the placebo group.⁸⁸ Until data are available from such trials, careful search for infectious processes and use of biocompatible dialysis membranes and ultrapure water are recommended. Restriction of catheter use is also important; short daily dialysis with better fluid status was associated with decreasing C-reactive protein levels compared with conventional hemodialysis.⁸⁹ Volume status should be carefully monitored.

Oxidative Stress

Oxidative stress probably plays a role in mediating CVD in CKD. Two placebo-controlled interventional studies showed that vitamin E⁹⁰ and N-acetylcysteine⁹¹ decreased the number of cardiovascular events in hemodialysis patients. Unfortunately, both studies were small and of limited duration. As N-acetylcysteine administration led to reduced atheromatous lesions in an apoE knockout model of CKD-enhanced atherosclerosis, adequately powered randomized trials with antioxidative treatment strategies are warranted.

Vascular Calcification

In the prospective Treat-to-Goal study, 200 hemodialysis patients were randomized to receive calcium-containing phosphate binders (calcium acetate or carbonate) or the calcium-free binder sevelamer.⁹² For calcium binder patients, coronary and aortic calcification progressed during the year but was halted for sevelamer-treated patients. In the subsequent Dialysis Clinical Outcomes Revisited trial, sevelamer versus calcium-based phosphate binder therapy did not reduce mortality.⁹³ As vitamin D treatment is associated with improved survival in dialysis patients,⁹⁴ vitamin D insufficiency should also be considered. KDOQI and KDIGO targets for parathyroid hormone, calcium, and phosphate are discussed in Chapter 81.

Hyperhomocysteinemia

Despite suggestive epidemiologic data linking hyperhomocysteinemia to adverse outcomes, to date, all randomized clinical trials on homocysteine lowering with use of folic acid or multivitamin supplementation have shown no benefit in the general population or in CKD patients.⁹⁵

Revascularization

There is a strong inverse relationship between renal function and survival after percutaneous coronary intervention (PCI)⁹⁶ and coronary artery bypass graft surgery (CABG).⁹⁷ Coronary revascularization complicated by acute kidney injury is associated with

excess mortality; operative mortality for non-ESRD patients who require acute dialysis after cardiac surgery is 44%.⁹⁸

Data comparing coronary revascularization with medical therapy in CKD are limited by their retrospective, observational nature; studies have not always compared revascularization with optimal medical therapy, including β -blockers. Observational studies suggest lower mortality in CKD (including dialysis) patients undergoing coronary revascularization compared with no revascularization.^{99,100} A *post hoc* analysis of CKD patients in the FRISC II (Fast Revascularization During Instability in Coronary Artery Disease) trial indicated a superior outcome with an early invasive strategy in acute coronary syndrome compared with conservative management.¹⁰¹

The optimal coronary revascularization method for CKD patients remains controversial because of absence of adequate clinical trial data; the largest studies are derived from observational data, particularly the USRDS database. A *post hoc* analysis of CKD patients enrolled in the ARTS (Arterial Revascularization Therapies Study)¹⁰² trial found similar outcomes for CABG or multivessel PCI with non-drug-eluting stents for death, myocardial infarction, or stroke; unsurprisingly, CABG was associated with less repeated revascularization. Dialysis patient survival after CABG was better than after PCI with non-drug-eluting stents,¹⁰³ but 2-year mortality was still very high at 44% (versus 52% for PCI). Preliminary data from USRDS studies indicate that drug-eluting stents provide the best 1-year survival for dialysis patients, but unadjusted long-term survival is best after CABG and increases with number of arteries bypassed and use of the internal mammary artery as a graft conduit. Because of higher periprocedural surgical mortality, short-term dialysis patient survival after PCI is better. However, for dialysis patients with four or more vessels bypassed, including use of internal mammary artery grafting, survival outcome more than 6 months after CABG is superior to drug-eluting stents. The best outcome thus depends on the length of postprocedure follow-up, and the optimal revascularization strategy may depend on particular clinical circumstance (a patient with a limited life expectancy might choose a treatment associated with less morbidity and only a short-term survival advantage). In elderly non-dialysis-dependent CKD patients, preliminary USRDS data indicate better 2-year survival with drug-eluting stents (with an 18% reduction in mortality compared with CABG).¹⁰⁴ In the general population, one proven advantage of drug-eluting stents (compared with non-drug-eluting stents) is lower incidence of in-stent restenosis. In dialysis patients, reliance on clinical surrogates (e.g., chest pain) for detection of restenosis can be problematic and lead to underestimation of the true incidence. The most complete angiographic follow-up of drug-eluting stents (performed in Japanese dialysis patients) noted 22% to 31% angiographically detected incidence of restenosis with drug-eluting stents and 24% to 37% with non-drug-eluting stents.^{105,106} Clinically inapparent restenosis is a rationale for surveillance stress imaging to detect occult restenosis as part of our management strategy for dialysis patients undergoing PCI (see Fig. 78.13).

Anemia in Chronic Kidney Disease

Iain C. Macdougall, Kai-Uwe Eckardt

Anemia is an almost universal complication of chronic kidney disease (CKD). It contributes considerably to reduced quality of life of patients with CKD and has been associated with a number of adverse clinical outcomes. Before the availability of recombinant human erythropoietin (rHuEPO, or epoetin), patients on dialysis frequently required blood transfusions, exposing them to the risks of iron overload, transmission of viral hepatitis, and sensitization, which reduced the chances of successful transplantation. The advent of rHuEPO in the late 1980s changed this situation completely. The ability to correct anemia has shown that its consequences go beyond general fatigue and reduced physical capacity to affect a broad spectrum of physiologic functions. Thus, there is a strong rationale for managing anemia in CKD patients, and yet the optimal treatment strategies are still incompletely defined. Apart from therapy with erythropoiesis-stimulating agents (ESAs), iron replacement is essential for anemia management. Importantly, CKD patients require target thresholds of iron parameters different from those for normal individuals to ensure optimal rates of red cell production. The costs of anemia management are considerable; therefore, a rational and careful consideration of the risks and benefits is mandatory.

PATHOGENESIS

Renal anemia is typically an isolated normochromic, normocytic anemia with no leukopenia or thrombocytopenia. Both red cell life span and the rate of red cell production are reduced, but the latter is more important. The normal bone marrow has considerable capacity to increase the rate of erythropoiesis, and the reduction in erythrocyte life observed in association with CKD would normally be easily compensated. However, this EPO-induced compensatory increase in erythrocyte production is impaired in CKD. Serum EPO levels remain within the normal range and fail to show the inverse exponential relationship with blood oxygen content characteristic of other types of anemia. EPO is normally produced by interstitial fibroblasts in the renal cortex, in close proximity to tubular epithelial cells and peritubular capillaries.^{1,2} In addition, hepatocytes and perisinusoidal Ito cells in the liver can produce EPO (Fig. 79.1). Hepatic EPO production dominates during fetal and early postnatal life but cannot compensate for the loss of renal production in adult organisms. Subtle changes in blood oxygen content induced by anemia reduce environmental oxygen concentrations, and high altitude stimulate the secretion of EPO through a widespread system of oxygen-dependent gene expression.²⁻⁴ Central to this process is a family of hypoxia-inducible transcription factors (HIFs). The two most important members of this family, HIF-1

and HIF-2, are composed of an oxygen-regulated α subunit (HIF-1 α or HIF-2 α) and a constitutive β subunit. The production of HIF-1 α and HIF-2 α is largely independent of oxygen, but their degradation is related to cellular oxygen concentrations. Hydroxylation of specific prolyl and asparagyl residues of HIF- α , for which molecular oxygen is required as a substrate, determines HIF proteasomal destruction and inhibits its transcriptional activity. Apart from EPO, more than 100 HIF target genes have been identified. HIF-2, rather than HIF-1, is the transcription factor primarily responsible for the regulation of EPO production.^{5,6}

The role of renal EPO production in the pathogenesis of renal anemia is supported by the observation that anemia is particularly severe in anephric individuals. However, the mechanisms impairing renal EPO production in diseased kidneys remain poorly understood. The production capacity for EPO remains significant, even in end-stage renal disease. Thus, patients with anemia and CKD can respond with a significant increase in EPO production to an additional hypoxic stimulus.¹ The main problem therefore appears to be a failure of EPO production in response to chronically reduced hemoglobin (Hb) concentrations. In line with this view, endogenous EPO production can be induced in CKD patients by pharmacologic inhibition of HIF degradation (see later discussion).

EPO is a glycoprotein hormone consisting of a 165-amino acid protein backbone and four complex, heavily sialylated carbohydrate chains.^{1,2} The latter are essential for the biologic activity of EPO *in vivo* because partially or completely deglycosylated EPO is rapidly cleared from the circulation. This is also why rHuEPO has to be manufactured in mammalian cell lines because bacteria lack the capacity to glycosylate recombinant proteins.

EPO stimulates red cell production through binding to homodimeric EPO receptors, which are primarily located on early erythroid progenitor cells, the burst-forming units erythroid (BFU-e) and the colony-forming units erythroid (CFU-e). Binding of EPO to its receptors salvages these progenitor cells and the subsequent earliest erythroblast generation from apoptosis, thereby permitting cell division and maturation into red blood cells.⁷ Inhibition of red cell production by uremic inhibitors of erythropoiesis may also contribute to the pathogenesis of renal anemia, although they have so far not been identified. Nevertheless, dialysis *per se* can improve renal anemia and the efficacy of ESAs. Moreover, the interindividual dose requirements for ESAs vary significantly among CKD patients, and the average weekly dose is much higher than estimated production rates of endogenous EPO in healthy individuals. An alternative view to the accumulation of inhibitors of erythropoiesis in CKD is that in

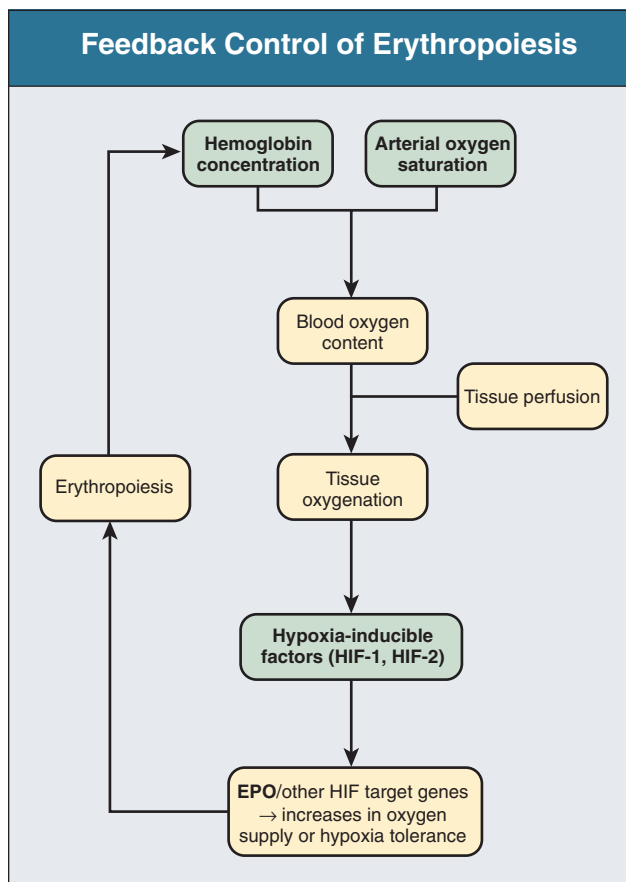

Figure 79.1 Feedback control of erythropoiesis.

many patients, there is overlap between renal anemia and the anemia of chronic disease, which is characterized by inhibition of EPO production and EPO efficacy as well as by reduced iron availability, mediated through the effects of inflammatory cytokines.⁸ Recently, hepcidin was discovered as a key mediator of iron metabolism. Its hepatic release is upregulated in states of inflammation; it simultaneously blocks iron absorption from the gut and promotes iron sequestration in macrophages.⁹

EPIDEMIOLOGY AND NATURAL HISTORY

In general, there is a progressive increase in the incidence and severity of anemia with declining renal function. The reported prevalence of anemia by CKD stage varies significantly and depends to a large extent on the definition of anemia and whether study participants are selected from the general population, are at high risk for CKD, are diabetic, or are already under the care of a physician. Data from the National Health and Nutrition Examination Survey (NHANES) showed that the distribution of Hb levels starts to fall at an estimated glomerular filtration rate (eGFR) of less than 75 ml/min per 1.73 m² in men and 45 ml/min per 1.73 m² in women (Fig. 79.2).¹⁰ The prevalence of Hb values below 13 g/dl increases below a threshold eGFR of 60 ml/min per 1.73 m² in men and 45 ml/min per 1.73 m² in women in the general population. Among patients under regular care and known to have CKD, the prevalence of anemia was found to be much greater, with mean Hb levels of 12.8 ± 1.5 (CKD stages 1 and 2), 12.4 ± 1.6 (CKD stage 3), 12.0 ± 1.6 (CKD stage 4), and 10.9 ± 1.6 (CKD stage 5).¹¹ Although anemia develops largely independently of the etiology of kidney disease, there

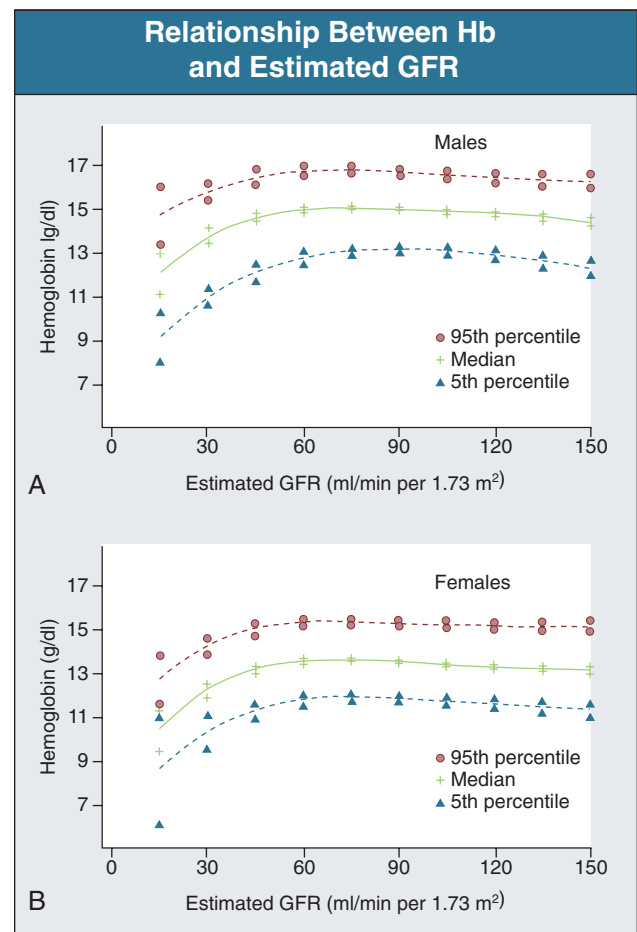

Figure 79.2 Relationship between hemoglobin (Hb) concentration and estimated glomerular filtration rate (GFR). Data are from a cross-sectional survey of individuals randomly selected from the general U.S. population (NHANES III). Results and 95% confidence interval are shown for males (A) and females (B) at each estimated GFR interval. (From reference 11.)

are two important exceptions. Diabetic patients develop anemia more frequently, at earlier stages of CKD, and more severely at a given level of renal impairment.^{12,13} Conversely, in patients with polycystic kidney disease, Hb is on average higher than in other patients with similar degrees of renal failure, and polycythemia may occasionally develop.¹

Many patients not yet on dialysis still receive no specific treatment for their anemia. In patients on dialysis, in contrast, average Hb values have steadily increased during the past 15 years, following the advent of EPO and the development of clinical practice guidelines for anemia management.^{12,13} The average Hb value, however, varies considerably between countries, reflecting considerable variability in practice patterns (Fig. 79.3).¹⁴ Moreover, Hb values vary considerably between patients in the same treatment setting as well as within patients, and at each time a large proportion of patients continues to have Hb values below recommended target levels (see later discussion).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnosis of anemia and the assessment of its severity are best made by measuring the Hb concentration rather than the hematocrit. Hb is a stable analyte that is measured directly in a standardized fashion, whereas the hematocrit is relatively

Figure 79.3 Mean hemoglobin (Hb) levels and percentage of patients with Hb levels below 11 g/dl who have been on dialysis therapy for more than 180 days and at the time of starting dialysis, by country. Data are from the Dialysis Outcomes and Practice Patterns Study, phase II (DOPPS 2), and are derived from 308 randomly selected, representative dialysis facilities. Note that there are marked differences between countries, but at least one fourth and up to three fourths of dialysis patients and, in most countries, more than two thirds of patients starting chronic dialysis have Hb values below the recommended lower target of 11 g/dl. ESRD, end-stage renal disease. (Modified from reference 14.)

unstable, indirectly derived by automatic analyzers, and lacking in standardization. Within-run and between-run coefficients of variation in automated analyzer measurements of Hb are one half and one third those for hematocrit, respectively.¹²

There is considerable variability in the Hb threshold used to define anemia. According to the most recent definition in the Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines, anemia should be diagnosed at Hb concentrations of less than 13.5 g/dl in adult men and less than 12.0 g/dl in adult women.¹² These values represent the mean Hb concentration of the lowest 5th percentile of the sex-specific general adult population. In children, age-dependent differences in the normal values have to be taken into account. Normal Hb values are increased in high-altitude residents.¹² Adjustment is not recommended for age in adults.

In addition to the Hb value, the evaluation of anemia in CKD patients should include a complete blood count with red blood cell indices (mean corpuscular Hb concentration [MCHC], mean corpuscular volume [MCV]), white blood cell count (including differential), and platelet count. Although renal anemia is typically normochromic and normocytic, deficiency of vitamin B₁₂ or folate may lead to macrocytosis, whereas iron deficiency or inherited disorders of Hb formation (such as thalassemia) may produce microcytosis. Macrocytosis with leukopenia or thrombocytopenia suggests a generalized disorder of hematopoiesis caused by toxins, nutritional deficit, or myelodysplasia. Hypochromia probably reflects iron-deficient erythropoiesis. An absolute reticulocyte count, which normally ranges between 40,000 and 50,000 cells/ μ l of blood, is a useful marker of erythropoietic activity.

Iron status tests should be performed to assess the level of iron in tissue stores or the adequacy of iron supply for erythropoiesis. Although serum ferritin is so far the only available marker of storage iron, several tests reflect the adequacy of iron for erythropoiesis, including transferrin saturation, MCV, and MCHC; the percentage of hypochromic red blood cells (PHRC);

and the content of Hb in reticulocytes (CHr). Storage time of the blood sample may elevate PHRC, and MCV and MCHC are below the normal range only after long-standing iron deficiency.

It is important to identify anemia in CKD patients because it may signify nutritional deficits, systemic illness, or other conditions that warrant attention, and even at modest degrees, anemia reflects an independent risk factor for hospitalizations, cardiovascular disease, and mortality.¹² The diagnosis of renal anemia, that is, an anemia caused by CKD, requires careful judgment of the degree of anemia in relation to the degree of renal impairment and exclusion of other or additional causes. Because there is significant variability in the degree of anemia in relation to the impairment in renal function, no simple diagnostic criteria can be applied. Causes of anemia other than EPO deficiency should be considered when (1) the severity of anemia is disproportionate to the impairment of renal function, (2) there is evidence of iron deficiency, or (3) there is evidence of leukopenia or thrombocytopenia. Concomitant conditions such as sickle cell disease may exacerbate the anemia, as can drug therapy. For example, inhibitors of the renin-angiotensin system may reduce Hb levels by (1) direct effects of angiotensin II on erythroid progenitor cells,¹⁵ (2) accumulation of *N*-acetyl-seryl-lysyl-proline (Ac-SDKP), an endogenous inhibitor of erythropoiesis in patients treated with angiotensin-converting enzyme (ACE) inhibitors,¹⁶ and (3) reduction of endogenous EPO production, potentially due to the hemodynamic effects of angiotensin II inhibition. Myelosuppressive effects of immunosuppressants may further contribute to anemia.¹⁷ The measurement of serum EPO concentrations is usually not helpful in the diagnosis of renal anemia because there is relative rather than absolute deficiency, with a wide range of EPO concentrations for a given Hb concentration that extends far beyond the normal range of EPO levels in healthy, nonanemic individuals. Abnormalities of other laboratory parameters should be looked for, such as a low MCV or MCHC (may indicate an underlying hemoglobinopathy), a high MCV (may

Secondary Effects of Anemia Correction on the Cardiovascular System
Reduction in high cardiac output
Reduced stroke volume
Reduced heart rate
Increase in peripheral vascular resistance
Reduction in anginal episodes
Reduction in myocardial ischemia
Regression of left ventricular hypertrophy
Stabilization of left ventricular dilation
Increase in whole blood viscosity

Figure 79.4 Secondary effects of anemia correction on the cardiovascular system.

indicate vitamin B₁₂ or folate deficiency), or an abnormal leukocyte or platelet count (may suggest a primary bone marrow problem, such as myeloma or myelodysplastic syndrome), and further tests should be performed as indicated to explore these potential conditions. However, when there are no such pointers to other confounding causes of anemia and iron deficiency has been excluded, a trial with rHuEPO or its derivatives is warranted, even when the eGFR is only moderately reduced.

CLINICAL MANIFESTATIONS

In the early clinical trials of EPO performed in the late 1980s, the mean baseline Hb concentration was about 6 to 7 g/dl, and this progressively increased to about 11 or 12 g/dl after treatment. Patients subjectively felt much better, with reduced fatigue, increased energy levels, and enhanced physical capacity, and there were also objective improvements in cardiorespiratory function.¹⁸ Thus, it is now clear that many of the symptoms previously attributed to the “uremic syndrome” are indeed due to the anemia associated with CKD (Figs. 79.4 and 79.5). Although the avoidance of blood transfusions and improvement in quality of life are obvious early changes, there are also possible effects on the cardiovascular system (see Fig. 79.4). The physiologic consequences of long-standing anemia are an increase in cardiac output and a reduction in peripheral vascular resistance. Anemia is a risk factor for the development of left ventricular hypertrophy in CKD patients and thought to exacerbate left ventricular dilation. Sustained correction of anemia in CKD patients results in a reversal of most of these cardiovascular abnormalities, with the notable exception of left ventricular dilation. Once the left ventricle is stretched beyond the limits of its elasticity, correction of anemia cannot reverse this.¹⁹ It may, however, prevent further progression in some patients. Other effects of anemia correction reported in clinical trials include improvements in quality of life, cognitive function, sleep patterns, nutrition, sexual function, menstrual regularity, immune responsiveness, and platelet function.

There has been considerable debate in recent times about the optimal target range of Hb in CKD patients. The improvement in quality of life with increasing Hb concentrations supports a level above 10 to 11 g/dl in all CKD patients,^{12,13} but some studies have indicated increased risks associated with attempts to

Other Secondary Effects of Anemia Correction

completely correct anemia. No survival benefit is evident at a higher level of anemia correction,²⁰⁻²² although quality of life and exercise capacity may be greater. Thus, there is a possible trade-off between improved quality of life and increased cost and risk for harm, so that a target level of Hb above 13 g/dl should be avoided.¹²

TREATMENT

Erythropoiesis-Stimulating Agents

Epoetin Therapy

Manufacture of rHuEPO is achieved by gene transfer into a suitable mammalian cell line such as Chinese hamster ovary cells or induction of the human gene in a hepatoma cell line. The early clinical trials of rHuEPO were conducted with both EPO alfa and EPO beta. Like the endogenous hormone, rHuEPO consists of a 165–amino acid backbone with one O-linked and three N-linked glycosylation chains. Invariably, however, there are some differences in the glycosylation pattern between different preparations of rHuEPO and the endogenous hormone. Several formulations of EPO are now available, including “biosimilar” EPO preparations, which have been developed after patent expiry of the innovator compounds. Other “copy” EPOs are available elsewhere in the world (e.g., China, India, Peru, Argentina, Russia, and Cuba), which are not necessarily produced to the same regulatory standards as the EPO preparations marketed in the United States and Europe. Another EPO that was initially developed for the European market was EPO delta, which differed from other EPOs in its glycosylation pattern because it was produced in a human fibrosarcoma cell line.

Before 1998, EPO alfa in Europe was formulated with human serum albumin, but because of a change in European regulations, this was replaced with polysorbate 80. EPO beta is formulated with polysorbate 20, along with urea, calcium chloride, and five amino acids as excipients. The importance of the formulation of the EPO products was highlighted in 2002 with an upsurge in cases of antibody-mediated pure red cell aplasia in association with the subcutaneous use of EPO alfa after its change of for-

mulation. Patients affected by this complication develop neutralizing antibodies against both rHuEPO and the endogenous hormone, which result in severe anemia and transfusion dependence.²³ The cause of this serious complication in which there is a break in B-cell tolerance remains obscure, although it seems likely that factors such as a breach of the cold storage chain were relevant, and the subcutaneous application route was a prerequisite; circumstantial evidence also suggested that rubber stoppers of prefilled syringes used in one of the albumin-free EPO alfa formulations may have released organic compounds that acted as immunologic adjuvants.²⁴ Although this unfortunate combination of adverse factors was specific for one compound, a low baseline rate of pure red cell aplasia also occurs with EPO beta and darbepoetin alfa.

The EPOs are administered either intravenously or subcutaneously. The bioavailability after intraperitoneal administration (in peritoneal dialysis patients) is too low. The earliest clinical trials of EPO used intravenous injections two or three times per week. This was partly due to the short half-life of EPO (6 to 8 hours after intravenous administration)²⁵ and partly due to the convenience for the patient on dialysis. With use of this regimen, 90% of patients show a significant increase in Hb concentration. Good iron management is pivotal for the success of EPO therapy (see later discussion). Adverse effects of EPO therapy are uncommon, apart from a moderate increase in blood pressure and an increased rate of vascular access thrombosis. Whereas these effects are probably dependent to a large degree on the increase in Hb concentrations, there are some concerns that ESA therapy may enhance thrombogenicity and tumor growth in patients with malignant disease as well as exacerbate vascular events in CKD independently of Hb concentrations.

Although the bioavailability of subcutaneous EPO is between 20% and 30%, the prolonged half-life after subcutaneous compared with intravenous administration allows less frequent injections. Furthermore, the dose required to achieve the same Hb response is about 30% lower with subcutaneous compared with intravenous administration.²⁶ There appears to be little difference between the thigh, arm, or abdomen as injection sites.

Darbepoetin Alfa

Darbepoetin alfa is a second-generation ESA that is a sialylated analogue of EPO, possessing two extra *N*-linked glycosylation chains. This property confers greater metabolic stability and a lower clearance rate *in vivo*, and the elimination half-life of this compound in humans after a single intravenous administration is three times greater than that of epoetin alfa (25.3 hours versus 8.5 hours). Thus, this agent can generally be given less frequently than the standard epoetins, with dosing intervals of once weekly and once every alternate week.²⁷ In contrast to the epoetins, dosage requirements for darbepoetin alfa for the correction of anemia and maintenance of Hb concentration in CKD patients are the same for intravenous and subcutaneous administration. The conversion factor for switching patients from epoetin alfa or beta to darbepoetin alfa is usually quoted as 200:1, but there may be considerable variability in this, depending on the patient population, the dose, and the route of administration.²⁵

C.E.R.A. (Methoxypolyethylene Glycol-Epoetin Beta)

Alternative bioengineering techniques to prolong the half-life of EPO further resulted in the development of C.E.R.A., which is a pegylated derivative of epoetin beta with an elimination half-life of around 130 hours when it is administered either intrave-

nously or subcutaneously. Phase III studies suggested that many patients are able to be maintained with once-monthly administration of C.E.R.A., and a superiority study (PATRONUS) suggested greater efficacy with this frequency of administration compared with once-monthly dosing of darbepoetin alfa when it is administered intravenously to hemodialysis patients.²⁸

Other Erythropoiesis-Stimulating Agents

Several other ESAs are currently in clinical development,²⁹ including Hematide and the “HIF stabilizers.”

Hematide is an erythropoietin mimetic peptide, the amino acid sequence of which is completely unrelated to native or recombinant erythropoietin,²⁹ although it shares the same functional and biologic properties of EPO. Hematide is currently in phase III of its clinical development program. The potential advantages of this compound include a greater *ex vivo* stability, allowing storage at room temperature; a prolonged pharmacodynamic action, allowing once-monthly administration; a different immunogenicity profile with no cross-reactivity between Hematide and anti-EPO antibodies, allowing effective treatment of anti-EPO antibody-mediated pure red cell aplasia³⁰; and a simple manufacturing process involving synthetic peptide chemistry.

The HIF stabilizers are competitive inhibitors of HIF prolyl hydroxylases²⁹ and asparagyl hydroxylase, enzymes involved in the metabolism of HIF and its transcriptional activity. The HIF stabilizers therefore cause an increase in endogenous EPO production.²⁹ The first of the prolyl hydroxylase inhibitors is currently being tested in phase II studies, and these drugs are orally active.²⁹ There is much discussion about whether these agents will upregulate not only EPO gene expression but also other HIF target genes, such as those involved in iron metabolism and neoangiogenesis. Whereas some of these effects may facilitate an increase in Hb concentrations, the long-term consequences of these potential additional effects have not been established.^{29,31}

Initiation of and Maintenance Therapy with Erythropoiesis-Stimulating Agents

According to current guidelines, all CKD patients should be investigated and treated if their Hb concentration decreases to less than 11 g/dl.^{12,13} Before ESA therapy is started, it is essential to exclude and to correct causes of anemia other than EPO deficiency, such as hematinic deficiencies (Fig. 79.6). If the ferritin concentration is below 100 µg/l, iron supplementation may be administered either first or concurrently. Iron is best given by intravenous administration, although oral iron can be considered in patients not yet on dialysis. Some patients may respond to intravenous iron alone (see later discussion). If the ferritin level is above 100 µg/l (in the absence of systemic inflammation) or there is a suboptimal response to iron, ESA therapy should be commenced. The usual starting dose of epoetin is about 25 to 50 IU/kg (e.g., 2000 IU) two or three times weekly, either by intravenous or subcutaneous administration. Within 3 to 4 days, an increase in the reticulocyte count is seen, and within 1 to 2 weeks, there is a significant rise in the Hb concentration, usually on the order of 0.25 to 0.5 g/dl per week. Thus, during the course of 1 month, a significant increase of 1 to 2 g/dl in the Hb concentration is usually achieved. If a patient fails to respond satisfactorily to ESAs, the dose is increased in stepwise upward titrations of 25% to 50%, and if there is still an inadequate response, causes of resistance to EPO therapy should be investigated (see later discussion). The optimal target range of Hb

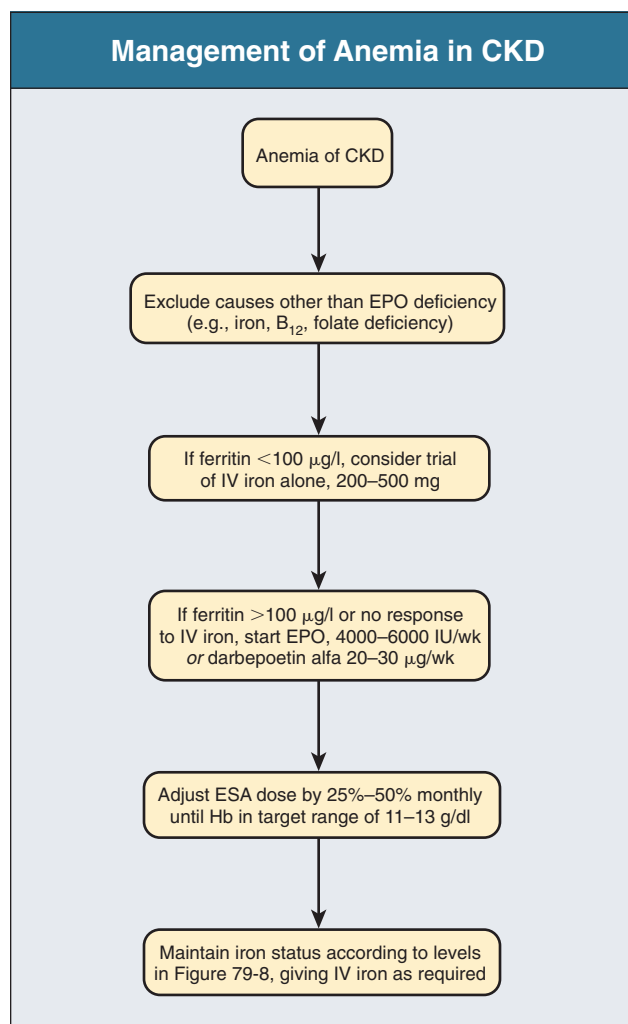

Figure 79.6 Management of anemia in patients with chronic kidney disease (CKD). EPO, erythropoietin; ESA, erythropoiesis-stimulating agent.

concentration for CKD patients is considered to be 11 to 13 g/dl¹² (see earlier discussion), and iron supplementation should be administered to maximize the response to ESA therapy (see later discussion). A possible starting dose of darbepoetin alfa is 20 to 30 µg once weekly intravenously or subcutaneously; an appropriate starting dose of C.E.R.A. is 30 to 60 µg once every 2 weeks intravenously or subcutaneously.

Hyporesponsiveness to Erythropoiesis-Stimulating Agents

There is no absolute definition of hyporesponsiveness to ESA therapy, but it is usually identified when the Hb concentration remains below 11 g/dl despite increasing doses of ESA. The causes of resistance to ESA therapy are listed in Figure 79.7, and it is important to correct them when possible. The major causes include iron deficiency (see later discussion), infection or inflammation,³² and underdialysis.³³ If the patient is self-administering (e.g., for peritoneal dialysis patients), poor adherence to or compliance with therapy must be excluded. If there is any doubt about the possibility of iron deficiency, a trial of intravenous iron may be useful. Vitamin B₁₂, folate, and thyroxine deficiency may be excluded easily by the appropriate laboratory tests, as may severe hyperparathyroidism. Aluminum toxicity is no longer a significant cause of ESA resistance. Depending on the ethnic

Causes of a Poor Response to ESA Therapy	
Major (Frequent)	Minor (Less Common)
Iron deficiency	Poor compliance, poor adherence to ESA therapy
Infection, inflammation Underdialysis	Blood loss Hyperparathyroidism Aluminum toxicity (rare nowadays) Vitamin B ₁₂ or folate deficiency Hemolysis Primary bone marrow disorders (e.g., myelodysplastic syndrome) Hemoglobinopathies (e.g., sickle cell disease) ACE inhibitors, angiotensin receptor blockers Carnitine deficiency Anti-EPO antibodies causing PRCA

Figure 79.7 Causes of a poor response to erythropoiesis-stimulating agent (ESA) therapy. ACE, angiotensin-converting enzyme; EPO, erythropoietin; PRCA, pure red cell aplasia.

origin of the patient, a hemoglobinopathy should be excluded by performing Hb electrophoresis. Some patients taking ACE inhibitors or angiotensin receptor blockers may require higher doses of ESA therapy, although it is rarely necessary or indeed advisable to stop these drugs. Primary bone marrow disorders, such as myelodysplastic syndrome, should be investigated by a bone marrow examination (aspirate and trephine) if all other causes have been excluded. A bone marrow test may also be necessary in the diagnosis of antibody-mediated pure red cell aplasia, although measurement of the reticulocyte count and anti-erythropoietin antibodies may provide an earlier clue.²³ If a patient receiving ESA therapy has a high reticulocyte count, the bone marrow is generating more than adequate quantities of new red cells, and bleeding or hemolysis should be investigated by means of upper gastrointestinal endoscopy, colonoscopy, or hemolysis screen (Coombs test, bilirubin measurement, lactate dehydrogenase levels, haptoglobin levels).

There is no defined upper dose limit of ESA, and doses of 60,000 IU per week of EPO are not uncommon in the United States, but there is recent concern that high doses of ESA may increase side effects independently of Hb concentrations by presumed pleiotropic effects and may enhance cardiovascular and other thrombotic events. However, because the requirement of high doses usually reflects a high degree of comorbidity and inflammation, it is difficult to establish the cause and effect of the association between high ESA doses and adverse outcomes; consequently, no “safe” upper dose level has been determined. Studies in cancer patients have found that targeting a normal Hb concentration with high ESA doses may also be associated with adverse outcomes compared with targeting a subnormal Hb target,^{34,35} but whether this is due to vascular complications or effects on tumor growth is still controversial. Although no study has investigated anemia management in patients with CKD and cancer, it appears reasonable to apply the subnormal Hb target recommendation for CKD patients also to this special group and to avoid high ESA doses. In patients with acute illness requiring hospitalization, Hb frequently falls despite continued ESA therapy, indicating increased blood loss and temporary hyporesponsiveness. The optimal management of anemia under these conditions remains unclear. Whereas cost considerations may

speak for withholding of ESA therapy until responsiveness is reestablished, it has also been proposed that doses should be increased in an attempt to overcome hyporesponsiveness. Very high doses have been demonstrated to be effective even in critically ill patients on intensive care units, but a pivotal trial³⁶ failed to demonstrate a reduction in transfusion requirements. From a practical point of view, and pending evidence to the contrary, it seems sensible to continue the same dose of ESA or to attempt one dose increase (e.g. doubling), but further dose escalations are probably not advisable or cost-effective.

Iron Management

Iron is an essential ingredient for heme synthesis, and adequate amounts of this mineral are required for the manufacture of new red cells. Thus, under enhanced erythropoietic stimulation, greater amounts of iron are used, and many CKD patients (particularly those on hemodialysis) have inadequate amounts of available iron to satisfy the increased demands of the bone marrow.³⁷ Even before the introduction of ESA therapy, many CKD patients were in negative iron balance as a result of poor dietary intake, poor appetite, and increased iron losses due to occult and overt blood losses (see Chapter 83). Losses in hemodialysis patients are up to 5 or 6 mg a day, compared with 1 mg in healthy individuals, and this may exceed the absorption capacity of the gastrointestinal tract, particularly when there is any underlying inflammation. Iron absorption capacity in patients with CKD is considerably lower than in nonuremic individuals, particularly in the presence of systemic inflammatory activity, and this is probably mediated by hepcidin upregulation (see earlier discussion).⁹ For this reason also, oral iron is ineffective in many CKD patients, and parenteral iron administration is required, particularly in those receiving hemodialysis.³⁷ However, even with these limitations of oral iron absorption, the cheap costs of using this route, along with convenience for the patient, often persuade physicians to try oral iron supplementation first in nondialysis patients; if, however, there is insufficient response after 2 to 3 months, intravenous iron should be administered.

Inadequate supply of iron to the bone marrow may be due to an absolute or a functional iron deficiency.³⁷ *Absolute* iron deficiency occurs when there are low whole-body iron stores, as indicated by a serum ferritin level less than 30 µg/L. *Functional* iron deficiency occurs when there is ample or even increased storage iron but the iron stores fail to release iron rapidly enough to satisfy the demands of the bone marrow. Several markers of iron status are available, but none of them is ideal (Fig. 79.8). The serum ferritin is a marker of storage iron but is spuriously raised in inflammatory conditions and liver disease. The transferrin saturation is a function of the circulating plasma iron in relation to the total iron-binding capacity and is often regarded as a better measure of available iron; however, levels can be highly fluctuant owing to significant diurnal variation in the measurement of plasma iron.³⁷ The percentage of hypochromic red cells and the CHr are red cell and reticulocyte parameters, respectively, that are indirect measures of how much iron is being incorporated into the newly developing or mature red cell.³³ No one measure of iron status is usually adequate to exclude iron deficiency, and the recommended levels for these measures are based on limited scientific evidence. Functional iron deficiency is usually diagnosed when there is a normal or increased ferritin level and a reduced transferrin saturation (<20%) or increased hypochromic red cells (>10%). The U.S.¹² and European¹³ guidelines on renal anemia management suggest

Markers of Iron Status in CKD Patients	
Test	Recommended Range
Serum ferritin	100–500 µg/L (CKD) 200–500 µg/L (HD)
Transferrin saturation	20%–40%
Hypochromic red cells	<10%
Reticulocyte hemoglobin content (CHr)	>29 pg/cell
Serum transferrin receptor	Not established
Erythrocyte zinc protoporphyrin	Not established

Figure 79.8 Markers of iron status and the recommended target ranges in chronic kidney disease (CKD).

that the ferritin level be maintained in the range of 200 to 500 µg/L, with an upper limit of 800 µg/L (see Fig. 79.8). Levels of ferritin above this threshold usually do not confer any clinical advantage and may exacerbate iron toxicity. The optimal transferrin saturation is above 20% to 30% to ensure a readily available supply of iron to the bone marrow. Several studies support the maintenance of the percentage of hypochromic red cells at levels of less than 6% and the CHr at levels greater than 29 pg/cell. Other measures of iron status, such as serum transferrin receptor levels and erythrocyte zinc protoporphyrin levels, are mainly research tools and have not been established in routine clinical practice.

Iron supplementation is often required in CKD patients. Oral iron is poorly absorbed in uremic individuals, and there is a high incidence of gastrointestinal side effects. Intramuscular administration of iron is not recommended in CKD, given the enhanced bleeding tendency, the pain of the injection, and the potential for brownish discoloration of the skin. Thus, intravenous administration of iron has become the standard of care for many CKD patients, particularly those receiving hemodialysis.³⁷ There are several intravenous iron preparations available worldwide, including iron dextran, iron sucrose, and iron gluconate. All of these preparations contain elemental iron surrounded by a carbohydrate shell, which allows them to be injected intravenously. The lability of iron release from these preparations varies, with iron dextran being the most stable, followed by iron sucrose and then iron gluconate. Iron is released from these compounds to plasma transferrin and other iron-binding proteins and is eventually taken up by the reticuloendothelial system.

In hemodialysis patients, it is easy and practical to give low doses of intravenous iron (e.g., 10 to 20 mg every dialysis session) or, alternatively, 100 mg weekly. In peritoneal dialysis and nondialysis CKD patients, however, such low-dose regimens are impractical, and larger doses may be administered. The more stable the iron preparation, the larger the dose administration rate that can be used. For example, 1 g of iron dextran may be given by intravenous infusion, whereas the maximum recommended dose of iron sucrose at any one time is 500 mg. For iron gluconate, doses in excess of 125 to 250 mg are best avoided. All intravenous iron preparations carry a risk for immediate reactions, which may be characterized by hypotension, dizziness, and nausea. These reactions are usually short-lived and caused by too large a dose given during too short a time. Iron dextran also carries the risk for acute anaphylactic reactions due to preformed dextran antibodies, and although this risk may be less with the

lower molecular weight iron dextrans, the potential for anaphylaxis still remains. Other, longer term concerns about intravenous administration of iron include the potential for increased susceptibility to infections and oxidative stress. Much of the scientific evidence for this has been generated in *in vitro* experiments, the clinical significance of which is unclear. Recently, two new iron preparations have become available for intravenous use (ferumoxytol in the United States and ferric carboxymaltose in Europe). Both of these compounds allow higher doses of intravenous iron to be administered rapidly as a bolus injection, without the need for a test dose.

There is emerging evidence that intravenous iron may improve the anemia of CKD in up to 30% of patients not receiving ESA therapy who have a low ferritin level.³⁸ In such patients, a response to intravenous iron alone may occur within 2 to 3 weeks of iron administration. In those already receiving ESAs, there is considerable evidence that concomitant intravenous iron may enhance the response to the ESAs and result in lower dose requirements.^{13,14,37}

Other Blood and Immune Disorders in Chronic Kidney Disease

Walter H. Hörl

Whereas anemia (see Chapter 79) is the clinically most prominent hematologic alteration in patients with chronic kidney disease (CKD), a variety of other changes also occur. These include altered platelet function, which together with abnormal coagulation may result in a uremic bleeding tendency but can also result in a prothrombotic state. In addition, leukocyte function is altered, resulting in increased susceptibility to infections and abnormal immune responses (e.g., after vaccinations).

PLATELET DYSFUNCTION AND COAGULATION DEFECTS

Normal hemostasis (Figs. 80.1 and 80.2) begins with platelet adhesion to vascular endothelium and requires a relatively vasoconstricted vessel wall, the integrity of platelet glycoproteins, and a normal quantity of large-molecular-weight, multimeric von Willebrand factor (vWF). Main platelet glycoproteins are GpIb, the platelet receptor for vWF, involved in platelet adhesion, and GpIIb/IIIa, the platelet receptor for fibrinogen, involved in platelet aggregation. Under static conditions, GpIb and vWF have no affinity for each other. However, these molecules develop a specific affinity for one another at high shear stress, resulting in arterial platelet adhesion. Aggregated fibrinogen-platelet mesh acts as a trap for binding and activation of other plasma clotting factors. The exposure of preceding clotting factors to tissue factors, present on damaged endothelial cells, catalyzes the conversion of prothrombin to thrombin, which converts fibrinogen to fibrin. Subsequent cross-linking of insoluble fibrin results in a stable hemostatic plug.

BLEEDING DIATHESIS IN UREMIA

Uremic bleeding caused by acquired platelet dysfunction is a major cause of morbidity and mortality in end-stage renal disease (ESRD) patients. The bleeding problems are characterized by abnormal prolongation of bleeding time and hemorrhagic symptoms, manifested usually as ecchymoses or petechiae in the skin, epistaxis, gastrointestinal or gingival oozing, or prolonged hemorrhage from needle puncture or postoperative sites. Hemorrhagic complications in ESRD patients may also be manifested as hemorrhagic pericarditis or hemorrhagic pleural effusion as well as intracranial, retroperitoneal, ocular, or uterine bleeding. The pathogenesis of platelet dysfunction in uremia is multifactorial (Fig. 80.3) and includes diminished adherence of platelets to vascular endothelium. In uremic patients, total platelet GpIb content is reduced, whereas the total content of GpIIb and GpIIIa is normal. Platelet membrane GpIb levels and GpIIb/IIIa

expression have been described as normal, decreased, or increased in uremic platelets. Plasma vWF level is normal or elevated in uremia. However, the observation that the administration of agents that increase plasma vWF or the factor VIII:vWF complex results in a shortening of prolonged bleeding time and a transient reversal of bleeding tendency in uremia suggests abnormalities in vWF metabolism, structure, or function. Mean platelet vWF antigen is reduced in uremia. Some ESRD patients display a decrease in all components, especially those with high molecular weight in their platelet vWF multimer pattern.

A variety of circulating plasma proteases, such as plasmin, cleave α chain of platelet GpIb. The resulting proteolytic degradation product glycocalicin contains binding sites for thrombin and vWF. Elevated plasma glycocalicin levels in uremic patients may contribute to diminished binding of uremic platelets to subendothelium due to the vWF binding site of glycocalicin. Furthermore, glycocalicin contains the thrombin binding site of GpIb, which may also contribute to diminished platelet function in uremia.

Low GpIb expression on resting platelets obtained from patients with CKD correlates with the severity of impaired kidney function. However, GpIb expression in uremic platelets increases after stimulation. In contrast, GpIIb/IIIa expression on resting uremic platelets is normal but reduced after stimulation, indicating hyporesponsiveness of the uremic platelets.

The ability to bind both vWF and fibrinogen to glycoproteins is reduced in uremia because of a conformational change in the GpIIb/IIIa receptor. Improvement of fibrinogen binding to GpIIb/IIIa by hemodialysis (HD) treatment suggests that uremic toxins, such as methylguanidine, guanidinosuccinic acid, phenolic acid, and hydroxyphenylacetic acid, also contribute to platelet dysfunction. HD and peritoneal dialysis (PD) correct platelet abnormalities at least partly, because conventional dialysis therapy does not remove all uremic toxins effectively. Interactions between platelets and HD membranes may alter platelet membrane receptors for vWF and fibrinogen, thus preventing normal platelet-vessel wall and platelet-platelet interactions. This can be demonstrated by a more prolonged bleeding time, a more decreased platelet responsiveness to thrombin, and a decreased platelet agglutination in response to ristocetin immediately after the HD procedure. Thus, heparin administered during HD treatment is not alone responsible for the prolonged bleeding time immediately after HD. Platelet contact with the artificial surfaces may result in GpIb internalization, which may also occur during platelet activation.

Prostacyclin and nitric oxide (NO) inhibit platelet function, modulate vascular tone, and affect platelet-vessel wall interaction as well as platelet-platelet interaction. Uremic platelets generate

Figure 80.1 Platelet adhesion and aggregation. Platelets are pushed peripherally toward the vascular wall by red blood cells traversing centrally through the blood stream. Damage to the vessel wall results in a disruption of the nonthrombogenic endothelial cell lining and exposure of subendothelial structures. Whereas collagen supports initial platelet adhesion (and subsequent aggregation), von Willebrand factor (vWF) deposition on the subendothelium serves as the main anchor for platelet adhesion through platelet GpIb receptor. Postadhesion conformational change in platelet GpIIb/IIIa receptor (fibrinogen/vWF receptor) results in interlinking platelet aggregation.

Figure 80.2 Clotting cascade. Expansion of the inset in Figure 80.1 shows the clotting cascade that takes place at the damaged vessel wall. Exposure of subendothelial tissue factor, present on pericytes and fibroblasts, allows eventual activation of prothrombin (factor II) to thrombin. Thrombin converts fibrinogen to fibrin, activates fibrin cross-linking, stimulates further platelet aggregation, and activates anticoagulant protein C. Naturally occurring anticoagulants antithrombin III, protein C, and protein S help maintain control and counterbalance on coagulation. *Site of anticoagulant effect for antithrombin III. †Site of anticoagulant effect for protein C–protein S complex.

more NO than platelets obtained from healthy subjects do. Uremic plasma induces NO synthesis in endothelial cells. Bleeding tendency in uremic patients is related to the increased platelet nitric oxide synthase (NOS) activity. The NOS substrate L-arginine inhibits platelet aggregation, whereas the NOS inhibitors *N*^G-monomethyl-L-arginine (L-NMMA) and *N*^G-nitro-L-arginine methyl ester (L-NAME) restore platelet adhesion and

aggregation. Inhibition of NOS by L-NMMA restores the increased bleeding time in experimental uremia to normal.

Renal anemia is another determinant of the prolonged bleeding time in ESRD patients. Within the normal circulation, red blood cells increase platelet–vessel wall contact by displacing platelets away from the axial flow and toward the vessel wall. Red blood cells improve platelet function by releasing adenosine

Pathogenesis of Platelet Dysfunction in Uremia

Platelet abnormalities

Alterations in membrane fluidity
 Reduction in intracellular ADP and serotonin
 Enhanced intracellular cAMP
 Impaired release of β -thromboglobulin and ATP
 Increased NO production
 Increased intracellular Ca^{2+} (due to secondary hyperparathyroidism)
 Abnormal mobilization of platelet Ca^{2+}
 Defective cyclooxygenase activity
 Reduced thromboxane A_2 generation
 Decreased platelet factor 3 availability
 Reduced total GPIb content (with increased glycosialix formation)
 Reduced GPIIb/IIIa after stimulation
 Diminished responsiveness to platelet agonists
 Decreased clott retraction
 Aggregation abnormalities (mostly hyperaggregation)
 Abnormal platelet adherence

Uremic toxins

Anemia

vWf abnormalities

Vessel abnormalities

Drugs (β -lactam antibiotics, nonsteroidal anti-inflammatory drugs, antiplatelet agents)

Figure 80.3 Pathogenesis of platelet dysfunction in uremia. ADP, adenosine diphosphate; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; NO, nitric oxide; vWF, von Willebrand factor.

diphosphate (ADP) and inactivating prostacyclin. Vasodilating effects of prostacyclin and NO increase vessel luminal diameter and decrease peripheral dispersion of platelets and their contact with the vessel wall. Erythropoiesis-stimulating agents (ESAs) improve platelet function mainly through increasing hematocrit.

However, ESAs can also enhance the risk for thrombotic events through an increase in blood viscosity. Platelet aggregation in uremia is increased by ESAs even at a dose that does not influence hematocrit by the release of young platelets to the blood. Low-dose ESA therapy also improves impaired platelet aggregation in uremia stimulated by ADP and ristocetin (for review, see reference 1).

The hemorrhage risk of ESRD patients is evaluated by the determination of the bleeding time. It is the most sensitive indicator of the extent of platelet dysfunction and measures primary platelet adhesion to the vessel wall and correlates with the abnormal platelet-vessel wall interaction that characterizes uremic bleeding. Bleeding times of more than 10 to 15 minutes have been associated with high risk of hemorrhage.

PLATELET NUMBER IN UREMIA

Thrombocytopenia is a common finding in ESRD patients. The platelet number is reduced in 16% to 55% of the uremic patients. However, the platelet count is rarely less than $80 \times 10^9/\text{L}$, a platelet number generally considered adequate for normal hemostasis. In HD patients, the interaction of blood with the HD membrane material may lead to complement activation and transient thrombocytopenia during the dialysis procedure. In contrast, thrombocytopenia does not occur with biocompatible non-

complement-activating dialyzers. Heparin may induce antibody-mediated thrombocytopenia (see later discussion).

Reduced platelet half-life and low-normal platelet number in uremia suggest increased platelet turnover, which is reflected by an increased percentage of reticulated platelets. Healthy subjects have a mean of $2.77\% \pm 0.17\%$ reticulated platelets; PD and HD patients have a significantly higher mean percentage of reticulated platelets of $6.92\% \pm 0.68\%$ and $8.21\% \pm 0.36\%$, respectively. Shortened platelet survival in uremia may be the result of increased exposure of negatively charged phosphatidylserine. This signal is recognized by macrophages and promotes phagocytosis (for review, see reference 1).

CORRECTION OF UREMIC BLEEDING

The bleeding disorder of uremic patients has been classically defined as an acquired defect of primary hemostasis, characterized by prolongation of bleeding time. Several options are available to prevent or to treat uremic bleeding (Fig. 80.4).

Correction by Dialysis

Adequate dialysis ($Kt/V > 1.2$ in HD and $Kt/V > 1.7$ in PD patients) (see Chapters 90 and 92) and the use of biocompatible high-flux dialyzers in HD patients ameliorate prolonged bleeding times in ESRD patients and the risk of hemorrhagic complications, probably by removal of uremic plasma factors. Hemorrhagic problems are fewer with PD compared with HD. Deep tissue biopsies or invasive surgical procedures that require improved hemostasis should ideally be scheduled 12 to 24 hours after dialysis in HD patients. Residual anticoagulant effects last as long as $2\frac{1}{2}$ hours with use of unfractionated heparin (UFH) during HD or even longer with low-molecular-weight heparin (LMWH). In case of clinical urgency or high risk of postoperative bleeding, heparin use should be minimized, eliminated (using predilutional saline), or replaced by regional anticoagulation with citrate during HD. Protamine sulfate administration (1 mg per 100 U of heparin infused during 10 minutes) should be considered if there is marked HD-induced prolongation of the partial thromboplastin time and severe bleeding.

Correction of Anemia

The use of ESAs has diminished hemorrhagic problems in uremic patients. Increased intraoperative bleeding complications have been reported in ESRD patients with low preoperative hematocrit levels (see Fig. 80.4). In ESRD patients, intraoperative transfusion of packed red blood cells may cause or aggravate hyperkalemia. If surgery is elective, ESAs (in combination with intravenous iron therapy) may be administered preoperatively to raise the hemoglobin to the upper acceptable values (12 g/dl). The maintenance dose of ESAs and the average time to reach target hemoglobin levels are highly variable from patient to patient. International guidelines recommend partial correction of renal anemia in CKD patients, targeting hemoglobin levels between 10 and 12 g/dl (hematocrit 30% to 36%; see Chapter 79). It remains to be clarified whether a patient prepared for surgery may have a benefit or risk in pushing hemoglobin levels even higher preoperatively.

ESA therapy improves uremic bleeding tendency by several mechanisms:

- Displacement of platelets closer to the vascular endothelium with the increase in circulating red blood cells

Treatment and Prevention of Uremic Bleeding						
Treatment	Mechanism	Prescription	Dose	Onset of Action	Maximum Effect	Duration of Effect after Cessation
Dialysis	Removes uremic platelet receptor Allows re-expression of platelet vWF and fibrinogen receptors		Per Kt/V	Bleeding time may not improve immediately	Unknown	> 48 h
HD		Avoid surgery or biopsy immediately after HD	Kt/V > 1.2	Progressive improvement in bleeding time > 4 h after HD	Bleeding time returns to baseline > 16 h after HD	Until next HD
CAPD	Avoids platelet-dialyzer membrane interactions		Kt/V > 1.7	24 h	4–7 days	Unknown
Correct anemia (to a hematocrit 30%–36%)	Enhances platelet-vessel interaction	Transfusion of packed red blood cells Intravenous or subcutaneous epoetin	See Chapter 79	Immediate	To hematocrit 30%–36%	NA
Estrogen	Vasoconstriction: enhances platelet-vessel and platelet-platelet interaction	Intravenous, conjugated	0.6 mg/kg per day (3 mg total)	6 h	6 days	14 days
		Oral conjugated Topical (patch) estradiol	50 mg per day 50–100 mg patch q3.5/day	3–5 days 24–48 h	7 days 5–7 days	4 days unknown
DDAVP (arginine vasopressin; desmopressin)	Enhanced platelet adhesion by increasing vWF serum levels and vWF platelet receptors (GpIb).	Intravenous	0.3–0.4 µg/kg in 50 ml normal saline during 30 min	1 h		4–6 h
		Intranasal Subcutaneous	2–3 µg/kg 0.3 µg/kg	2 h	Unknown	Unknown
Cryoprecipitate	Enhances platelet adhesion by increasing vWF levels	Intravenous	10 U/30 min	1 h	4–8 h	24 h

Figure 80.4 Treatment and prevention of uremic bleeding. CAPD, continuous ambulatory peritoneal dialysis; HD, hemodialysis; vWF, von Willebrand factor.

- Increase in reticulated (metabolically active) platelets
- Increase in platelet aggregation
- Improvement of platelet signaling (and thereby better response to stimuli)
- Scavenging of NO by hemoglobin, resulting in increased platelet adhesion.²

Cryoprecipitate

Cryoprecipitate is a blood product rich in factor VII, vWF, and fibrinogen. In uremic patients at high risk of bleeding or with active bleeding, a beneficial effect of cryoprecipitate on bleeding time should occur within 4 to 12 hours. Disadvantages include the risk of exposure to various blood-borne pathogens and allergic reactions.²

Desmopressin

Desmopressin acetate (1-deamino-8-D-arginine-vasopressin, DDAVP) is a synthetic derivative of the antidiuretic hormone vasopressin. The compound has been shown to be useful in a variety of inherited and acquired hemorrhagic conditions, such as uremia, and in patients with hemostatic defects induced by therapeutic use of antiplatelet drugs, such as aspirin, dipyri-

damole, clopidogrel, or ticlopidine. Moreover, DDAVP shortens bleeding time and activated partial thromboplastin time (APTT) of patients receiving heparin. It is therefore helpful for the management of hemorrhagic complications during treatment with heparin. Desmopressin shortens the prolonged APTT and bleeding time by an increase in plasma levels of factor VIII and vWF. The increase in larger vWF–factor VIII multimers after infusion of DDAVP is associated with shortening of bleeding time. It also increases platelet GpIb expression.

Desmopressin is the most common agent used in uremic patients for bleeding disorders. The recommended doses range from 0.3 to 0.4 µg/kg administered intravenously in 50 ml normal saline during 20 to 30 minutes as a single infusion. Subcutaneous (0.3 µg/kg) or intranasal (2 to 3 µg/kg) routes of administration are also effective. One important advantage of DDAVP is its rapid onset of action in the setting of acute bleeding. Desmopressin decreases bleeding time within approximately 1 hour after administration. This advantage is important for CKD patients with prolonged bleeding time needing biopsies or major surgery. Disadvantages of DDAVP include tachypylaxis caused by depletion of vWF from endothelial stores even after one single dose, headache, facial flushing, and rare thrombotic events. Because of the short duration of DDAVP activity (4 to 6 hours), bleeding time tends to return to baseline within

24 hours, indicating that patients are once again at risk of bleeding.²

Estrogens

Estrogens are still used for the treatment of uremic bleeding. The hormones decrease production of L-arginine, which is a precursor of NO, resulting in less production of cyclic guanosine monophosphate as well as in an increased production of thromboxane A₂, and ADP is crucial for the formation of platelet plugs. Estrogens may also decrease antithrombin III and protein S and increase factor VII concentrations, indicating that estrogens also display effects on coagulation factors.² The recommended dose of conjugated estrogens needed to improve bleeding time and clinical bleeding in uremia is 0.6 mg/kg intravenously during 30 to 40 minutes once daily for 5 consecutive days. The time to onset of action is about 6 hours; the maximum effect is evident at 5 to 7 days. Conjugated estrogens are effective for 14 to 21 days. Oral and transdermal estrogen therapy has also been shown to be beneficial.² Side effects include flushes, hypertension, and abnormal liver function test results.

Tranexamic Acid

Tranexamic acid is an antifibrinolytic drug. In the majority of patients with ESRD, bleeding time improves or normalizes within 6 days of treatment with tranexamic acid (20 to 25 mg/kg per day) administered intravenously or orally. Improvement of bleeding time was observed as soon as 24 to 48 hours after intake of tranexamic acid. If other treatment options do not elicit the desired response, tranexamic acid may be added to the regimen. For example, DDAVP and tranexamic acid have concomitantly been used to prevent or to treat bleeding in patients with CKD.

HEPARIN-INDUCED THROMBOCYTOPENIA

Heparin-induced thrombocytopenia (HIT) type II is a serious immune-mediated complication of heparin therapy. Thrombocytopenia (mean platelet number, 60,000/mm³) due to platelet consumption usually occurs between 4 and 14 days after the administration of heparin and is associated with arterial ("white clot syndrome") and particularly venous thromboembolism in 20% to 50% of the cases. HIT type II should be considered whenever the platelet count falls by 50% in a patient receiving heparin. Even though these patients develop thrombocytopenia, the threat is not bleeding but thrombosis. Antibodies against the complex of heparin with platelet factor 4 are the cause of this devastating disease. These antibodies activate platelets in the presence of heparin.³ A negative HIT antibody test result does not exclude the diagnosis of HIT type II syndrome; a positive antibody test result does not prove it.

In contrast, HIT type I presents with nonimmune mild transient decrease in the platelet count (rarely <100,000/mm³) 1 to 4 days after initiation of heparin therapy. It occurs in 10% to 20% of patients without appreciable clinical consequences and usually resolves spontaneously even though heparin therapy is continued.

The diagnosis of HIT type II requires immediate substitution of heparin with an alternative anticoagulation for HD to prevent possible life-threatening complications. In addition, heparin skin ointments and heparin-coated catheters have to be avoided. The use of LMWH is also contraindicated because of a high rate

of cross-reactivity once UFH has induced HIT antibody formation.

In a summary of six trials performed in HD patients,⁴ a total of 21 patients were found to have a positive test result for the HIT antibody (2.6%); the percentage was lower with use of LMWH compared with UFH. Very few of the HD patients were noted to be thrombocytopenic ($n = 6$), and none had severe thrombotic complications. A recent survey reported a prevalence of 0.26 per 100 patients and an incidence of 0.32 per 100 patients of HIT type II syndrome in the U.K. HD population. Only 17% of the patients have had complications of HIT type II syndrome. Thirty-six percent of renal units used danaparoid as anticoagulant of choice for these patients.⁵ In HIT type II patients, warfarin should not be used until the platelet count has recovered.³

Alternative Anticoagulation for Hemodialysis Patients with Heparin-Induced Thrombocytopenia Type II

Danaparoid

Danaparoid, a heparinoid of 5.5 kd, consists of heparan sulfate (83%), dermatan sulfate, and chondroitin sulfate. It is used as an alternative anticoagulant in HD patients with HIT type II in Canada and the European community. Danaparoid binds to antithrombin and heparin cofactor II. It inhibits factor Xa more selectively than LMWH does.⁶ In 6.5% of patients with HIT, cross-reactivity against HIT antibodies may result in thrombocytopenia. For monitoring of danaparoid therapy, anti-Xa activity has to be measured. The half-life of the anti-Xa activity of danaparoid is 25 hours in patients with normal kidney function and is further prolonged in uremia. An antidote is not available.⁶

Lepirudin

Lepirudin is a recombinant hirudin preparation. It is mainly eliminated by the kidney. Thus, its half-life is markedly prolonged in patients with ESRD. After a single loading dose (0.1 mg/kg), therapeutic anticoagulation may persist for 1 week or even longer. Hirudin does not cross-react with HIT antibodies, but 44% to 74% of patients treated with hirudin for more than 5 days develop antihirudin antibodies. Antilepirudin antibodies are not necessarily associated with a decrease in efficacy. Only in 2% to 3% of patients with antilepirudin antibodies is an inhibitory effect seen, and dose adjustments are required. Target APTT is 1.5 to 2.5 times the normal value.^{6,7}

Argatroban

Argatroban is a potent arginine-derived synthetic thrombin inhibitor. It is metabolized primarily by the liver. Its half-life is only moderately extended in patients with impaired kidney function. Argatroban does not cross-react with HIT antibodies. A loading dose of 250 µg/kg before HD and a maintenance dose of 1.7 to 3.3 µg/kg per minute are recommended. Target APTT of argatroban-treated HD patients is 1.5 to 3.0 times mean of normal range.⁶

In critically ill patients with HIT type II and necessity for continuous renal replacement therapy (CRRT) due to acute renal failure, critical illness scores such as the Acute Physiology and Chronic Health Evaluation (APACHE) II, the Simplified Acute Physiology Score (SAPS) II, and the indocyanine green plasma disappearance rate (ICG-PDR) can help predict the

required argatroban maintenance dose for anticoagulation.⁸ Argatroban dosing during CRRT in those patients is recommended as follows: the loading argatroban dose is 100 µg/kg followed by a maintenance infusion rate (µg/kg per minute), which is

- $2.15-0.06 \times \text{APACHE II}$ (for APACHE II)
- $2.06-0.03 \times \text{SAPS II}$ (for SAPS II)
- $-0.35 + 0.08 \times \text{ICG-PDR}$ (for ICG-PDR)

Fondaparinux

Fondaparinux, a fully synthetic pentasaccharide, is a selective factor Xa inhibitor. Its half-life is prolonged in patients with impaired kidney function, but it is safe. Subgroup analysis of the Fifth Organization to Assess Strategies in Acute Ischemic Syndromes (OASIS 5) showed that benefits of fondaparinux over enoxaparin (when it is administered for non-ST-segment elevation acute coronary syndrome) are most marked among patients with renal dysfunction (GFR <58 ml/min per 1.73 m²) and are largely explained by lower rates of major bleeding with fondaparinux.⁹ In addition, fondaparinux had significant benefit in decreasing the composite outcome of death, myocardial infarction, and refractory ischemia at day 30 in this population of patients. It is, however, not yet recommended for use in patients with HIT type II.

Regional Anticoagulation with Citrate

Citrate infused into the arterial line during HD inhibits the coagulation cascade in the extracorporeal circulation by the chelation of calcium and magnesium. The local deficit in ionized calcium is corrected by calcium substitution into the venous line before the blood is reinfused to the patient. In HD patients, regional citrate anticoagulation reduces bleeding complications and improves biocompatibility of dialysis membranes compared with systemic anticoagulation with UFH or LMWH (see also Chapter 89).

THROMBOTIC EVENTS IN UREMIA

Apart from a bleeding tendency, uremic patients also have a thrombophilic tendency and an increased incidence of thrombotic events. In dialysis patients, this frequently is manifested as thrombosis at the site of vascular access as well as in the coronary, cerebral, and retinal arteries. Thrombophilia is due to both platelet hyperaggregability and hypercoagulability.

Platelet Hyperaggregability

Binding of activated factor V to platelet surface-exposed phosphatidylserine induces coagulation. In uremic patients receiving murine monoclonal antibody to CD3 as prophylaxis for graft rejection, platelet procoagulant activity increases by binding of anti-factor V/Va as a result of increased exposure of anionic phospholipids in platelets.

Platelet activation also results in shape change, activation of surface receptors for fibrinogen and other adhesion proteins, and secretion of platelet factor 4, β-thromboglobulin, thromboxane B₂, and serotonin as well as induction of procoagulant activity. In HD patients, a relationship between recurrent vascular access failure and increase in CD62P-positive platelets and an increase in fibrinogen receptor (PAC-1)-positive platelets has been demonstrated.

Chronically activated circulating platelets seen in ESRD patients interact with leukocytes and erythrocytes, resulting in platelet-erythrocyte aggregates and platelet-leukocyte aggregates.

Platelet-erythrocyte aggregates enhance platelet reactivity, as detected by their thromboxane B₂ formation and release of β-thromboglobulin. Low levels of platelet-erythrocyte aggregates are found in healthy subjects (1.2% ± 0.1%). This percentage increases approximately 6-fold in ESRD patients but approximately 8- or 10-fold during HD. Platelet-leukocyte aggregates trigger neutrophil oxidative burst.

Platelets release small particles, so-called platelet microparticles (PMPs), after they are activated. PMPs expose procoagulant proteins such as tissue factor and contain a membrane receptor for coagulation factor V. In addition, PMPs provide a highly catalytic surface for the prothrombinase reaction due to high amounts of negatively charged phospholipids at the outer membrane. Significantly higher PMP counts were detected in predialysis patients and in patients undergoing regular PD or HD compared with healthy subjects.³ The HD procedure does not affect PMP counts. However, rHuEPO therapy increases PMP release. Some studies suggest higher PMP counts in uremic patients with thrombotic events, but not all studies confirmed these findings (for review, see reference 1).

Hypercoagulability

Apart from enhanced platelet aggregability (see earlier discussion), hypercoagulability in uremic patients results from diminished protein C anticoagulant activity, deficient release of tissue plasminogen activator, and elevated plasma levels of antiphospholipid and anticardiolipin antibodies, anti-protein C and anti-protein S antibodies, factor VIII levels, prothrombin fragments 1 and 2, fibrinogen, homocysteine, and lipoprotein(a). ESRD patients suffer from thrombotic complications as the result of changes in the secondary hemostasis and impaired fibrinolytic system activity. Antiphospholipid antibodies can trigger activation of the coagulation cascade at the endothelial surface. These antibodies cross-react with protein C and protein S, rendering them functionally deficient (see also Antiphospholipid Antibody Syndrome in Chapter 27). Reduced antithrombin III activity in uremia results in increased thrombin formation. Activated factor V (factor Va) serves as a cofactor for the conversion of prothrombin to thrombin. Its inactivation occurs by activated protein C. Heterozygosity for factor V Leiden mutation occurs in 2% to 5% of the Western population. Its prevalence is not increased in CKD patients, but factor V Leiden deficiency increases the risk of thrombotic complications.

Antiplatelet Agents in Patients with End-Stage Renal Disease

Antiplatelet agents may prevent vascular access thrombosis often seen in ESRD patients (see also Chapter 87). Small studies of aspirin and sulfapyrazone, dipyridamole, or ticlopidine suggest effectiveness of these drugs in the prevention of vascular access thrombosis. However, antiplatelet agents may increase bleeding complications in ESRD patients with the well-known bleeding diathesis discussed before. In a prior randomized controlled trial of clopidogrel (75 mg/day) plus aspirin (375 mg/day) versus placebo in HD patients during a period of at least 2 years, there was no significant benefit of active treatment in the prevention of access thrombosis, but the cumulative incidence of bleeding events was significantly greater in the patients treated with clopidogrel plus aspirin.¹⁰ Early failure of fistulas due to thrombosis or inadequate maturation is a common problem among patients treated with HD. Clopidogrel (loading dose of 300 mg followed

by daily dose of 75 mg for 6 weeks starting within 1 day after fistula creation) has been shown to reduce the frequency of early thrombosis of new arteriovenous fistulas compared with placebo (12% versus 20%; RR, 0.6; $P = .02$).¹¹

In patients with non-ST elevation acute coronary syndrome, clopidogrel treatment (loading dose of 300 mg followed by 75 mg daily) was beneficial in all patients, but impairment of kidney function increased the risk of major or life-threatening bleeding.¹² In patients undergoing an elective percutaneous coronary intervention of a single vessel or multiple vessels, clopidogrel treatment for 1 year markedly reduced death, myocardial infarction, and stroke compared with placebo in patients with normal kidney function (10% versus 4%; $P < .001$) but not in those with CKD stage 2 or above.¹³ A *post hoc* analysis of the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management and Avoidance (CHARISMA) trial revealed that asymptomatic patients with diabetic nephropathy assigned to aspirin plus clopidogrel had significantly increased overall and cardiovascular mortality compared with those treated with aspirin and placebo. It was thus suggested that clopidogrel may be harmful in patients with diabetic nephropathy.¹⁴

Because antiplatelet agents such as aspirin, dipyridamole, clopidogrel, and ticlopidine increase bleeding time, these drugs should not be given within at least 72 hours before biopsies and major surgery. Other drugs that may increase the risk of intraoperative bleeding in uremic patients include β -lactam antibiotics, nonsteroidal anti-inflammatory drugs, and diphenhydramine.

Anticoagulant Therapy in Patients with End-Stage Renal Disease

Approximately 6% of ESRD patients at risk of thrombosis or thromboembolic events may have an indication for oral anticoagulants. However, these indications are usually by extrapolation from patients without CKD or mild CKD at best. Vitamin K antagonism (e.g., by warfarin or other coumarins) in dialysis patients is associated with a marked increase in the frequency of hemorrhages. Moreover, vitamin K antagonists in the dialysis population contribute to vascular and valvular calcifications.¹⁵ Thus, the value of long-term vitamin K antagonism, for example, in dialysis patients with atrial fibrillation, is currently not well established. Management of warfarin is challenging in patients with CKD because warfarin dose, anticoagulation control, and risk for hemorrhagic complications are influenced not only by genetic factors (such as the genes for cytochrome P-450 2C9 and vitamin K epoxide reductase complex 1) as in each patient population but also by the kidney function. Patients with stage 4 or stage 5 CKD require significantly lower warfarin dosages, spend less time with their international normalized ratio (INR) within the target range of 2 to 3, and are at a higher risk for overanticoagulation (INR >4) compared with patients with no, mild, or moderate CKD.¹⁶ These problems may even be aggravated in ESRD patients and particularly in those undergoing regular dialysis treatment.

With regard to the high risk of stroke in ESRD patients with atrial fibrillation and the conflicting data about oral anticoagulation, an individualized approach based on the Cardiac Failure, Hypertension, Age, Diabetes, and Stroke (CHADS₂) score, on the one hand, and the Outcome Bleeding Risk Index has been recommended.¹⁷ In other words, ESRD patients with atrial fibrillation and a high risk of ischemic stroke but low risk for bleeding events should receive oral anticoagulants, whereas

ESRD patients with atrial fibrillation and a low or moderate risk for stroke but high risk for bleeding complications should probably not be treated with oral anticoagulants.¹⁸

Standard oral anticoagulation with an INR between 2 and 3 is not sufficient to prevent clotting during HD. Additional low-dose LMWH or UFH is needed to facilitate adequate extracorporeal treatment.

IMMUNE DYSFUNCTION IN UREMIA

Uremia-related immune dysfunction is a complex interaction between alterations in both the innate and adaptive immune systems. In uremic patients, immune activation, characterized by elevated cytokine levels and acute-phase response, and immunosuppression, characterized by impaired responses to infections and poor development of adaptive immunity, coexist.

Pathogenesis

Immunosuppression

Altered Function of Polymorphonuclear Leukocytes ESRD is characterized by deranged functions of polymorphonuclear leukocytes. Polymorphonuclear leukocytes are cells of the first-line nonspecific immune defense and migrate to the site of infection along a chemotactic gradient. Polymorphonuclear leukocytes ingest the invading microorganisms by phagocytosis and kill them with proteolytic enzymes and toxic radicals produced during the oxidative burst. Disturbances of any essential polymorphonuclear leukocyte function increase the risk for infectious complications.¹⁹

Uremic toxins have been isolated from the ultrafiltrate of HD patients or the dialysis effluent of PD patients that inhibit specific neutrophil responses *in vitro*. Among these are soluble low- and high-molecular-weight molecules, including granulocyte inhibitory proteins with homology to immunoglobulin light chains and β_2 -microglobulin, monomers and dimers of free immunoglobulin light chains, angiogenin, complement factor D, ubiquitin, advanced glycation end products, retinol-binding protein, leptin, and resistin. These molecules have been found to interfere with polymorphonuclear leukocyte and lymphocyte functions, including reduced chemotaxis, adherence, oxidative burst activity in response to phagocytosis, and intracellular killing of bacteria.¹⁹ Advanced glycation end products are formed by the reaction of aldehyde or ketone groups of carbohydrates with amino acids. Accumulation of advanced glycation end products in uremia promotes inflammation but also immune dysfunction by the modulation of polymorphonuclear leukocyte apoptosis. Polyclonal free immunoglobulin light chains are usually excreted in the urine and thus accumulate in the serum of patients with progressive CKD. Monomers and dimers of free immunoglobulin light chains isolated from uremic patients inhibit stimulated glucose uptake (a measurement of the state of activation of phagocytic cells) and polymorphonuclear leukocyte chemotaxis. Free immunoglobulin light chains attenuate polymorphonuclear leukocyte apoptosis, contributing to preactivation of polymorphonuclear leukocytes and interfering with normal resolution of inflammation. By these mechanisms, polyclonal free immunoglobulin light chains contribute to the chronic inflammatory state seen in uremia. HD with newer, high cutoff dialyzers allows removal of large amounts of free immunoglobulin light chains, but the effect on polymorphonuclear leukocyte function and infections in HD patients remains unknown at present.

Immunologic functions in uremic patients are compromised by three different mechanisms targeting polymorphonuclear leukocytes²⁰: inhibition, pre-activation, and priming. Inhibition of immune cells on stimulation reflects diminished immune responses leading to infections or impairing the resolution of infectious complications. Priming of immune cells is an important physiologic mechanism controlling host defense responses. During priming of leukocytes by a primary agent such as oxidants, the functional response to a stimulus is amplified. Pre-activation of leukocytes in uremia reflects enhanced polymorphonuclear leukocyte activity under basal conditions but does not allow adequate response to a stimulus.

Dendritic Cell Function Uremia impairs blood dendritic cell function,²¹ a factor likely to contribute to the higher rates of infectious complications observed in these patients. Dendritic cells are antigen-presenting cells that coordinate both innate and adaptive immunity. The subsets of circulating dendritic cell precursors derived from CD34⁺ bone marrow hematopoietic progenitor cells in the peripheral blood include precursor myeloid dendritic cells and precursor plasmacytoid dendritic cells. Precursor myeloid dendritic cells are immunosurveillance cells, and precursor plasmacytoid dendritic cells are critical in antiviral and possibly antitumor immunity. Isolated myeloid dendritic cells and plasmacytoid dendritic cells from HD patients are functionally impaired *in vitro* with reduced cell surface costimulatory molecule expression and interferon- α production after appropriate stimulation. Myeloid dendritic cells incubated with uremic sera demonstrate impaired maturation and decreased allostimulatory capacity. Similarly, herpes virus-stimulated plasmacytoid dendritic cells incubated with uremic sera produced significantly less interferon- α compared with dendritic cells incubated in the control media. Improving clearance of small-molecular-weight uremic toxins by use of a more efficient dialysis membrane improved myeloid dendritic cell function but not plasmacytoid dendritic cell function. Thus, the immunodeficiency of HD patients is at least partially due to dialyzable uremic toxins.²¹ These data are in agreement with previous observations that HD patients exhibit significantly lower polymorphonuclear leukocyte killing than healthy subjects do and that HD treatment can partially improve this.

Immune Stimulation

Chronic Stimulation of the Inflammatory Response Chronic stimulation of the inflammatory response in uremia results from uremic toxins plus dialysis-related factors (such as interaction between blood and the dialyzer membrane, presence of endotoxins in the dialysate), access-related infection, periodontal disease, other chronic infections (e.g., nasal sinuses), and peritoneal dialysis solution (high glucose concentration, low pH, and presence of glucose degradation products). Vitamin D and calcitriol deficiency is a common finding in patients with CKD stages 3 to 5 (see Chapter 81). Pleiotropic effects of activated vitamin D and its analogues include a role of this hormone as a potent immunomodulator. The link between Toll-like receptors (TLRs) and vitamin D-mediated innate immunity suggests that differences in the ability of human populations to produce vitamin D may contribute to susceptibility to microbial infection. TLR activation in human macrophages upregulates expression of the vitamin D receptor and the vitamin D 1-hydroxylase genes, leading to induction of the antimicrobial peptide cathelicidin. Patients with low 25-hydroxyvitamin D are inefficient in supporting cathelicidin messenger RNA induction.²² However, controlled

randomized studies are needed to clarify the role of vitamin D deficiency and its correction for impaired host deficiency in uremia.

Infections in Patients with Chronic Kidney Disease

Infections are the main reason for hospitalization and the second common cause of death in ESRD patients. In addition, dialysis patients exhibit a higher annual mortality rate caused by sepsis compared with the general population. An increased risk of blood stream infection is also observed in older adults with non-dialysis-dependent CKD stages 4 and 5.²³ Infections develop primarily as a consequence of deranged functions of polymorphonuclear leukocytes (see earlier discussion). Other factors predisposing to infections include an inadequate response to vaccinations as a consequence of a deficient T lymphocyte-dependent immune response²⁰ and an impairment of blood dendritic cell function.²¹ A variety of additional factors, such as the accumulation of uremic toxins, iron overload, renal anemia, dialyzer bioincompatibility, vascular access-related infections, or vitamin D deficiency of ESRD patients, may also contribute to infections.¹⁹

VACCINATION IN PATIENTS WITH CHRONIC KIDNEY DISEASE

Hepatitis B Virus

Blood is a major vehicle for the transmission of the hepatitis B virus (HBV). Therefore, patients undergoing regular HD are at particularly high risk of exposure to HBV infection, with a wide variation in endemicity between the countries. In addition, immunodeficiency renders patients with ESRD susceptible to infection and subsequent disease. Uremia impairs not only the clearance of the virus but also antigen presentation, T-cell activation, and subsequent antibody production. Thus, responses to HBV vaccination range from 50% to 90% in this population of patients. HBV vaccination (Fig. 80.5) is recommended for all predialysis and dialysis patients, but the seroconversion rate (anti-HBs >10 IU/l) and adequate responses (anti-HBs >100 IU/l) are markedly lower, quite variable, and shorter lasting than in healthy immunocompetent subjects. Therefore, patients with CKD should undergo vaccination in the early stages of the disease when the primary immune response is still intact. Reasons for poor response to HBV vaccination in ESRD patients include cellular immunodeficiency, dialysis inadequacy, inflammation, malnutrition, diabetes mellitus, and older age.

Careful monitoring of antibody titers and booster doses are necessary to maintain protection against HBV. A cutoff of 100 IU/l is considered a necessary threshold for maintaining protection in immunocompromised patients. A study confirmed that seroprotection rates decrease rapidly over time in HD patients. It also documented, however, better persistence of circulating anti-HBs antibodies up to 42 months after primary vaccination with HBV-AS04 (HBV vaccine formulated with a new adjuvant system) compared with standard HBV vaccine (78% versus 51%). No difference in seroprotection rates was observed in the two groups 1 month after completion of the immunization course (92% versus 87%) or at month 12 and month 24, whereas it became significant at month 30 (85% versus 63%).²⁴

Different approaches have been used to overcome the nonresponsiveness of chronically uremic patients, such as the intra-

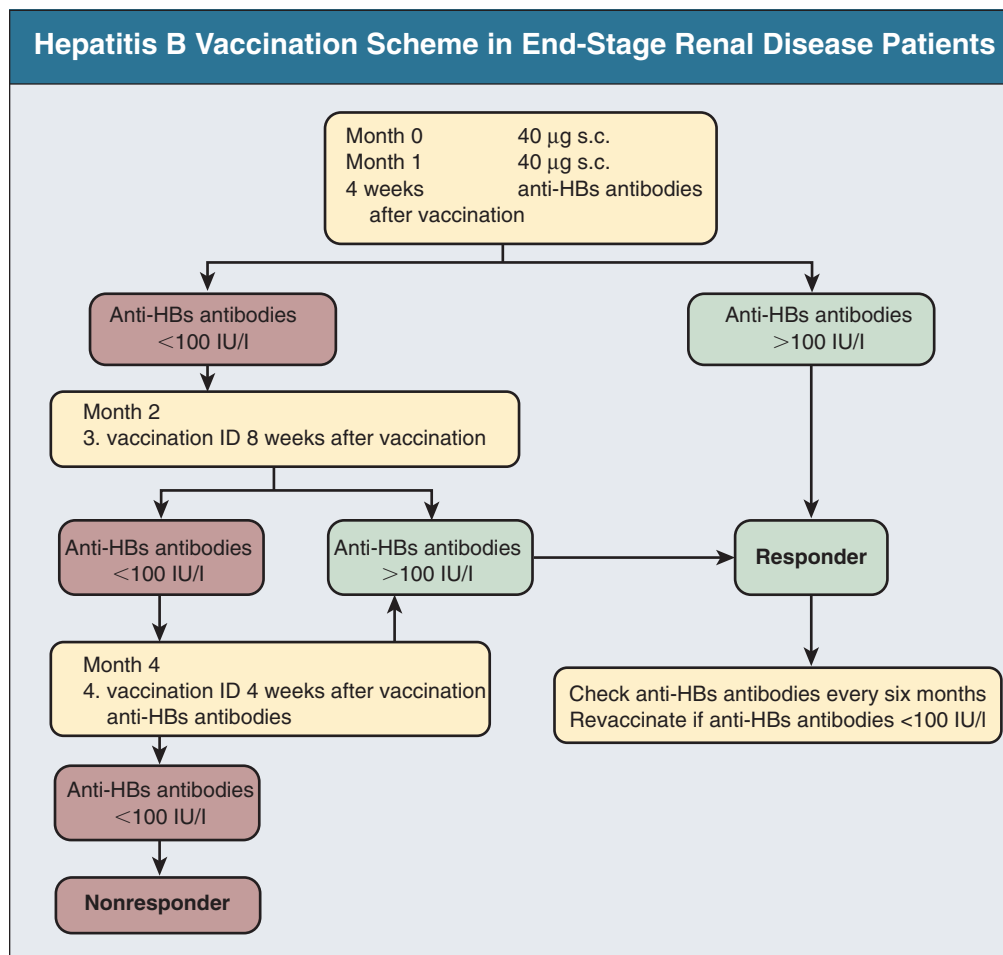

Figure 80.5 Hepatitis B vaccination scheme in end-stage renal disease patients. All patients receive three doses of hepatitis B vaccine, 40 µg subcutaneously. An additional dose is given if anti-HBs antibody response is less than 100 IU/l.

muscular administration of multiple doses or double doses, the coadministration of immunomodulators, and the intradermal administration of HBV vaccine. In a prospective open-label randomized controlled trial, HD patients nonresponsive to primary HBV vaccination were revaccinated with either intradermal (5 µg of vaccine every week for 8 weeks) or intramuscular (40 µg of vaccine at weeks 1 and 8) HBV vaccine. Seroconversion rates were 79% intradermally but only 40% intramuscularly ($P = .002$). There was also a trend toward longer duration of seroprotection with intradermal vaccination. It was concluded that intradermal vaccination should become the standard of care in this setting. However, it remains unclear whether the greater efficacy of intradermal vaccination is the cumulative effect of multiple injections or route of administration.²⁵

A variety of studies have demonstrated that granulocyte-macrophage colony-stimulating factor (GM-CSF) may be an effective adjuvant to HBV vaccine response in HD patients. GM-CSF induced a significant effect in terms of response rate and achievement of an earlier seroconversion to the vaccine in the overall populations examined, in renal failure patients, and in healthy subjects.²⁶ Because GM-CSF primarily acts on monocytes and dendritic cells, it may be reasonable to assume a direct effect of GM-CSF on antigen-presenting cells including dendritic cells to overcome dysfunctional antigen presentation/

costimulation and overall cellular function²¹ that leads to impaired antibody responses after HBV vaccination.

Influenza Virus

Chronic dialysis patients benefit from influenza vaccination in reducing mortality and hospitalization rate. Response to such a vaccination has been reported to be suboptimal or normal. A first vaccination of HD patients with the influenza vaccine was followed by protective hemagglutination antibody titers ($\geq 1:40$) in 95% of the vaccinees 1 month after vaccination. A booster dose of influenza vaccine did not improve the humoral response in this population of patients.²⁷ In 201 long-term HD patients and 41 healthy volunteers, the immunogenicity of a standard trivalent inactivated influenza vaccine was evaluated.²⁸ More than 80% of HD patients showed seroprotection 1 month after vaccination. Their immune response was not different from that of healthy volunteers. High serum ferritin level was the only parameter independently associated with a better vaccination-induced antibody response in HD patients, whereas nutrition, inflammation, and dialysis adequacy did not have a significant impact. Therefore, the clinical relevance of disturbances in acquired immunity in contemporary HD patients was questioned.²⁸

Pneumococcus

HD patients and patients after successful kidney transplantation respond well to antipneumococcal vaccination. However, these patients rapidly lose their serum antibody levels within 1 year after vaccination.²⁹ The percentage of responders depends on the definition of the adequate vaccine response. In 48 pediatric patients with CKD, an adequate vaccine response defined as a postimmunization level of specific pneumococcal serotype antibody of 0.35 µg/ml or higher, based on the World Health Organization's protective antibody concentration definition, was obtained in 100% of the patients. If an adequate vaccine response was defined as a fourfold increase over baseline for at least five of the seven antigens (serotypes 4, 6B, 9V, 14, 18C, 19F, 23F), protective antibody concentrations were found in 46% of non-dialysis CKD patients and in 38% of the patients undergoing regular dialysis therapy.³⁰

Other Vaccinations

Only 55% of CKD patients and 69% of HD patients show normal seroconversion rates after tetanus toxoid vaccination. Diphtheria vaccination results in a seroconversion rate of only 37%, and 33% of patients retain protective levels after booster administration.³¹ Almost all dialysis patients may develop protective antibodies after hepatitis A vaccination is administered either intramuscularly or subcutaneously. After administration of varicella vaccine, 85% of ESRD patients develop antibodies within the first 6 months, and 76% of patients have protective antibody titer at 1 year.

Bone and Mineral Metabolism in Chronic Kidney Disease

Kevin J. Martin, Jürgen Floege, Markus Ketteler

DEFINITION

Disturbances of mineral metabolism are common if not ubiquitous during the course of chronic kidney disease (CKD) and lead to serious and debilitating complications unless these abnormalities are addressed and treated. The spectrum of disorders includes abnormal concentrations of serum calcium, phosphate, and magnesium and disorders of parathyroid hormone (PTH) and vitamin D metabolism. These abnormalities as well as other factors related to the uremic state affect the skeleton and result in the complex disorders of bone known as renal osteodystrophy; it is now recommended that this term be used exclusively to define the bone disease associated with CKD. The clinical, biochemical, and imaging abnormalities heretofore identified as correlates of renal osteodystrophy should be defined more broadly as a clinical entity or syndrome called chronic kidney disease–mineral and bone disorder (CKD-MBD).¹ The spectrum of skeletal abnormalities seen in renal osteodystrophy (Fig. 81.1) includes the following:

- Osteitis fibrosa, a manifestation of hyperparathyroidism characterized by increased osteoclast and osteoblast activity, peritrabecular fibrosis, and increased bone turnover.
- Osteomalacia, a manifestation of defective mineralization of newly formed osteoid most often caused by aluminum deposition; bone turnover is decreased.
- Adynamic bone disease, a condition characterized by abnormally low bone turnover.
- Osteopenia or osteoporosis.
- Combinations of these abnormalities termed mixed renal osteodystrophy.
- Other abnormalities with skeletal manifestations (e.g., chronic acidosis, β_2 -microglobulin amyloidosis).

EPIDEMIOLOGY

The prevalence of the various types of renal bone disease in patients with end-stage renal disease (ESRD) is illustrated in Figure 81.2.² In patients on hemodialysis, osteitis fibrosa and adynamic bone disease now occur with almost equal frequency. In contrast, in patients on peritoneal dialysis, the adynamic bone lesion predominates. Osteomalacia represents only a small fraction of cases in either group but is more common in certain ethnic groups, particularly Indo-Asians. The abnormalities of the skeleton start relatively early in the course of CKD.

PATHOGENESIS

Several biochemical and hormonal abnormalities that are encountered during the course of CKD contribute to renal bone disease and can be affected by efforts at prevention and therapy. The

major factors that are operative in early CKD may vary as CKD progresses. Similarly, the predominance of one particular pathogenetic mechanism over another may contribute to the heterogeneity of bone disorders. We therefore discuss separately the two major entities, namely, high- and low-turnover osteodystrophy.

Osteitis Fibrosa: Hyperparathyroidism: High-Turnover Renal Bone Disease

Elevated levels of PTH in blood and hyperplasia of the parathyroid glands are seen early in CKD. Whereas the level of free (i.e., non-protein bound) calcium in blood is normally the principal determinant of PTH secretion, during the course of CKD, several metabolic disturbances also alter the regulation of the secretion of PTH.

Abnormalities of Calcium Metabolism

There are three main body pools of calcium: the bony skeleton (mineral component), the intracellular pool (mostly protein bound), and the extracellular pool (see Chapter 10). The calcium in the extracellular pool is in continuous exchange with that of bone and cells and is altered by diet and excretion. Calcium metabolism depends on the close interaction of two hormonal systems: PTH and vitamin D. Perturbations of both of these systems occur during the course of CKD, with adverse consequences on the skeleton. Total serum calcium tends to decrease during the course of CKD as a result of phosphate retention and decreased production of 1,25-dihydroxyvitamin D (calcitriol) from the kidney, decreased intestinal calcium absorption, and skeletal resistance to the calcemic action of PTH, but the levels of free calcium remain within the normal range in most patients (Fig. 81.3)³ as a result of compensatory hyperparathyroidism. Because calcium is a major regulator of PTH secretion, persistent hypocalcemia is a powerful stimulus for the development of hyperparathyroidism and also contributes to parathyroid growth.

Abnormalities of Phosphate Metabolism

With progressive CKD, phosphate is retained by the kidney. However, hyperphosphatemia usually does not become evident before CKD stage 4. Until then, compensatory hyperparathyroidism and increases in circulating fibroblast growth factor 23 (FGF-23) result in increased phosphaturia, maintaining serum phosphate levels in the normal range.⁴

One mechanism by which phosphate retention may lead to hyperparathyroidism (Fig. 81.4) is by a decrease in serum free calcium, which in turn stimulates the secretion of PTH. Thus, a new steady state is achieved in which serum phosphate is restored to normal at the expense of a sustained high level of PTH. This cycle is repeated as renal function declines until

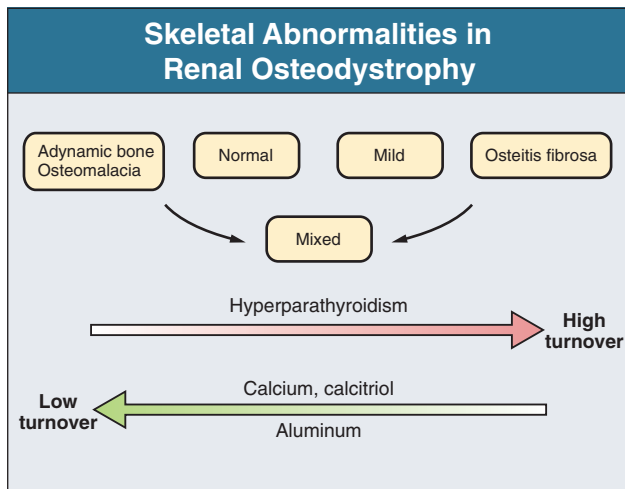

Figure 81.1 The spectrum of renal osteodystrophy. The range of skeletal abnormalities in renal bone disease encompasses syndromes with both high and low bone turnover.

Figure 81.2 Prevalence of renal osteodystrophy in patients with end-stage renal disease. HPT, high-turnover renal osteodystrophy; MUO, mixed uremic osteodystrophy; LTOM, low-turnover osteomalacia; ADYN, adynamic bone disease. (From reference 37.)

sustained and severe hyperparathyroidism is present. Second, phosphate retention leads to decreased production of calcitriol by the kidney, either directly or by increasing the levels of FGF-23 (which decreases the activity of 1α -hydroxylase). The decrease in calcitriol allows increases in PTH gene transcription by direct action and also decreases intestinal calcium absorption, leading to hypocalcemia, which in turn stimulates PTH secretion. Third, hyperphosphatemia is associated with resistance to the actions of calcitriol in the parathyroid glands, which also favors the development of hyperparathyroidism and also induces resistance to the actions of PTH in bone. Finally, phosphate *per se* appears to affect PTH secretion independently of changes in serum calcium or serum calcitriol.^{5,6} Phosphate may also have an effect on parathyroid growth independent of serum calcium.^{7,8} Regardless of the mechanism by which phosphate retention causes hyperparathyroidism, restriction of dietary phosphate in proportion to the decrease in glomerular filtration rate (GFR) can prevent the development of hyperparathyroidism. Current evidence suggests that FGF-23 also acts directly on the parathyroid gland and has inhibitory effects on PTH secretion and

Figure 81.3 Ionized calcium and parathyroid hormone (PTH) levels in chronic renal failure. Levels of ionized calcium are maintained in advancing renal failure by progressive increases in PTH.

parathyroid growth.^{9,10} This would suggest that the main effects of FGF-23 on the pathogenesis of hyperparathyroidism appear to be indirect as a result of the potent effect of FGF-23 to decrease calcitriol production. These various actions may explain the association of the levels of FGF-23 with patient outcome.¹¹

Abnormalities of Vitamin D Metabolism

The conversion of 25-hydroxyvitamin D to its active metabolite 1,25-dihydroxyvitamin D occurs mainly in the kidney by the enzyme 1α -hydroxylase. Extrarenal production of calcitriol also occurs and contributes to the circulating levels of calcitriol. Renal calcitriol production progressively declines during the course of CKD as a result of several mechanisms (Fig. 81.5).

Calcitriol production is compromised in the setting of CKD by a reduction in 25-hydroxyvitamin D levels¹² and the decrease in GFR, which further limits the delivery of 25-hydroxyvitamin D to the site of the 1α -hydroxylase in the proximal tubule. Phosphate retention either directly or by inducing an increase in FGF-23 also decreases the activity of 1α -hydroxylase. Finally, it appears that circulating PTH fragments may also directly decrease calcitriol production. The resultant decreased levels of calcitriol contribute to the pathogenesis of hyperparathyroidism by several direct and indirect mechanisms (Fig. 81.6). Low levels of calcitriol directly release the gene for PTH from suppression by the vitamin D receptor and allow increased PTH secretion. In many tissues, vitamin D regulates its own receptor by positive feedback; the vitamin D receptor content is decreased in parathyroid tissue in CKD. Administration of calcitriol has been shown to increase the vitamin D receptor content in the parathyroid glands coincident with the suppression of PTH secretion. Studies *in vitro* have shown that calcitriol is a negative growth regulator of parathyroid cells; therefore, calcitriol deficiency in CKD may facilitate parathyroid cell proliferation. Other direct consequences of low levels of calcitriol that contribute to the pathogenesis of secondary hyperparathyroidism include increasing the parathyroid set point for calcium-regulated PTH secretion and, possibly, decreasing the expression of calcium receptors.

Low levels of calcitriol may also promote the development of hyperparathyroidism indirectly. First, decreased calcitriol

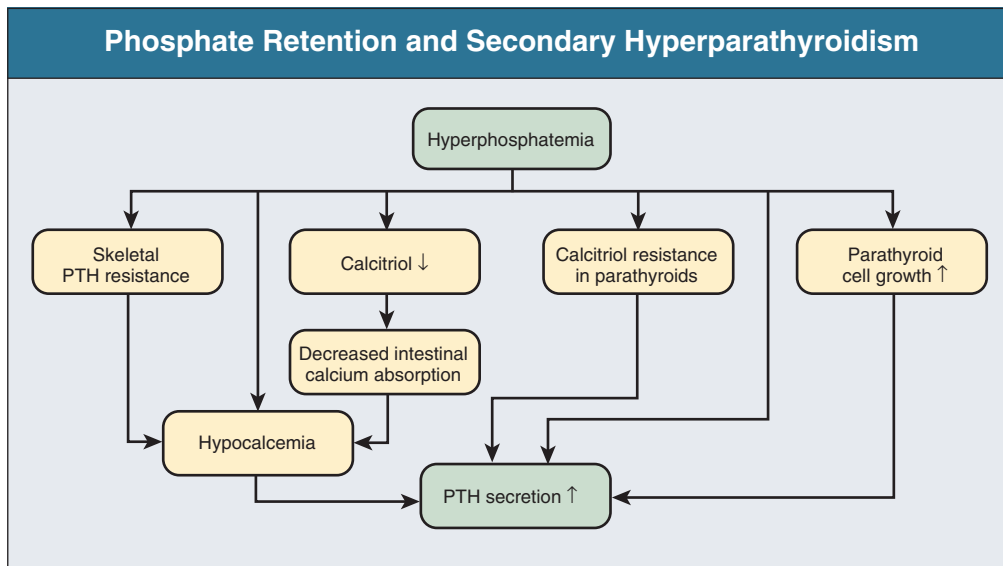

Figure 81.4 Role of phosphate retention in the pathogenesis of secondary hyperparathyroidism. Hyperphosphatemia stimulates parathyroid hormone (PTH) secretion indirectly by inducing hypocalcemia, skeletal resistance to PTH, low levels of calcitriol, and calcitriol resistance. Hyperphosphatemia also has direct effects on the parathyroid gland to increase PTH secretion and parathyroid cell growth.

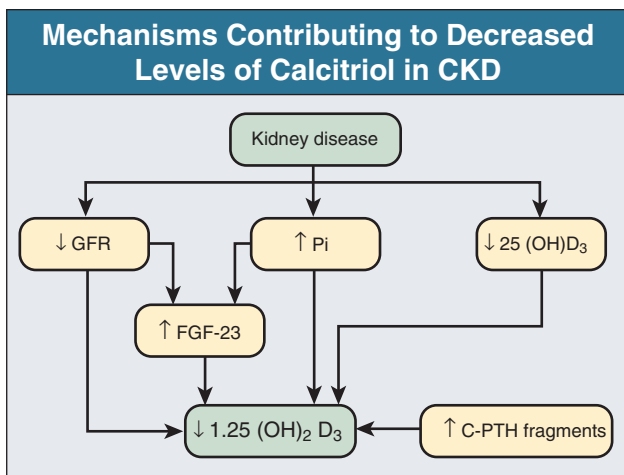

Figure 81.5 Mechanisms contributing to decreased levels of calcitriol in CKD.

production as renal function decreases can lead to progressive reductions in intestinal absorption of calcium, leading to hypocalcemia and stimulation of PTH release. Second, low levels of calcitriol have been implicated in skeletal resistance to the calcemic actions of PTH, which may also contribute to the development of hyperparathyroidism.

Abnormalities of Parathyroid Gland Function

There are intrinsic abnormalities in parathyroid gland function in the course of CKD in addition to those caused by hypocalcemia, low levels of calcitriol, and skeletal resistance to the actions of PTH (Fig. 81.7).

Parathyroid hyperplasia is an early finding in CKD. In experimental models, hyperplasia begins within a few days after the induction of CKD and can be prevented by dietary phosphate restriction or by the use of calcimimetic agents.^{7,13} Resected parathyroids from patients with severe hyperparathyroidism have nodular areas throughout the gland, which represent monoclonal expansions of parathyroid cells.¹⁴ Within these nodules, there is decreased expression of vitamin D receptors as well as of calcium receptors.^{15,16} The decreased expression of calcium

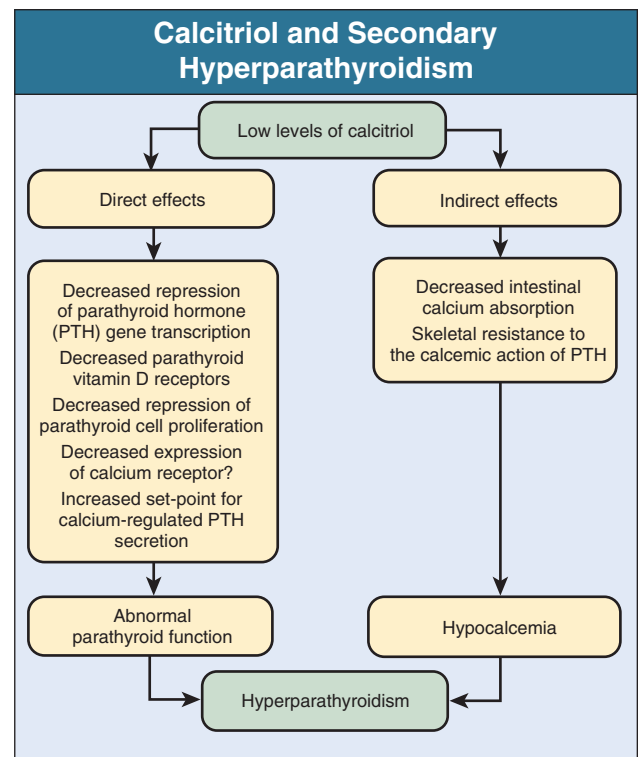

Figure 81.6 Role of low levels of calcitriol in the pathogenesis of secondary hyperparathyroidism.

receptors renders efforts to therapeutically affect these enlarged hyperplastic glands difficult.

The parathyroid calcium receptor is centrally involved in the regulation of PTH secretion by calcium.¹⁷ Its expression and synthesis are decreased in parathyroid glands from hyperparathyroid subjects,¹⁶ leading to altered calcium-regulated PTH secretion. Increased concentrations of calcium are required *in vitro* to suppress PTH release from the parathyroid cells of uremic patients compared with those of normal controls. Thus, the set point for the concentration of calcium required to decrease PTH release by 50% appears to be increased.

Abnormal Skeletal Response to Parathyroid Hormone

In patients with CKD, there is an impaired response of serum calcium to the administration of PTH and a delay in the recovery from induced hypocalcemia in the presence of larger increments in PTH levels. Thus, in CKD, the skeleton is relatively resistant to the calcemic actions of PTH. The resultant decrease in serum calcium levels stimulates PTH secretion and contributes to the pathogenesis of secondary hyperparathyroidism. Factors involved in the skeletal resistance to PTH in CKD include decreased levels of calcitriol, downregulation of the PTH receptor, and phosphate retention. In addition, circulating fragments of PTH, truncated at the N-terminus, which still react in the older, second-generation two-site PTH assays, may serve to oppose the calcemic actions of PTH, probably acting at a receptor for the C-terminal region of PTH.^{18,19}

CLINICAL MANIFESTATIONS OF HIGH-TURNOVER RENAL OSTEODYSTROPHY

Clinical manifestations of hyperparathyroidism are usually nonspecific and are often preceded by biochemical or imaging abnormalities. Aches and pains are common manifestations, often nonspecific in nature, and occur in the lower back, hips, and legs, aggravated by weight bearing. Acute, localized bone pain can also become manifested and may be suggestive of acute arthritis. Pain around joints may be caused by acute periartthritis, which is associated with periarticular deposition of calcium phosphate crystals, especially in patients who suffer from marked hyperphosphatemia. The symptoms may be confused clinically

with gout or pseudogout and often respond to nonsteroidal anti-inflammatory drugs (NSAIDs). The gradual onset of muscle weakness is also common in patients with ESRD. Many factors are probably involved in its pathogenesis, including hyperparathyroidism and abnormalities of vitamin D. The arthropathy associated with β_2 -microglobulin amyloidosis (see later discussion) should be considered in the differential diagnosis in very long term dialysis patients.

Bone deformities may occur in patients with severe hyperparathyroidism, particularly in children. In adults, deformities arise as a consequence of fractures, sometimes induced by brown tumors (see later discussion); the axial skeleton is most commonly affected. This can lead to kyphoscoliosis or chest wall deformities. Slipped epiphysis may occur in children, and frank rachitic features are occasionally evident. Growth retardation is also common in children, and although some improvement has been shown with calcitriol, this has not been the universal finding.

Extraskelatal calcifications are frequently encountered in patients with advanced CKD and are aggravated by persistent elevation of the calcium-phosphate product. Most commonly, vascular calcifications are seen, but calcifications may also occur in other sites, such as the lung, myocardium, and periarticular areas (Fig. 81.8).

In the skin, hyperparathyroidism can be manifested as pruritus (discussed in detail in Chapter 84). Rarely, it can also underlie the development of calciphylaxis, or calcific uremic arteriolopathy (discussed in detail in Chapter 84; see Figs. 84.6 and 84.7).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

In addition to the clinical manifestations of renal osteodystrophy, a variety of biochemical and radiographic techniques are helpful to establish the specific diagnosis and to serve as a guide for the initiation and adjustment of therapeutic interventions. Although bone biopsy is not widely used in clinical practice, it remains the gold standard for the diagnosis of renal osteodystrophy.

Serum Biochemistry

The levels of free calcium and phosphate in serum are usually normal in patients with mild to moderate CKD. Usually in stage 4 CKD, the levels of serum calcium tend to fall, and hyperphosphatemia is manifested. Hypercalcemia may result from the administration of large doses of calcium-containing antacids or

Parathyroid Abnormalities in Chronic Kidney Disease
Parathyroid gland hyperplasia: diffuse, nodular
Decreased expression of vitamin D receptors
Decreased expression of calcium receptors
Increased set-point of calcium-regulated parathyroid hormone secretion

the administration of vitamin D metabolites. Patients with severe hyperparathyroid bone disease may develop hypercalcemia. It is important to differentiate between the different causes of hypercalcemia in the setting of CKD (see Chapter 10) because the management will vary greatly according to the cause. Also, the levels of serum calcium and phosphate, when used alone, are not useful in predicting the specific type of bone disease.

Parathyroid Hormone

Measurements of PTH are important for diagnostic purposes and for therapeutic guidance in the management of renal osteodystrophy. With renal impairment, there is accumulation of circulating PTH fragments, which complicates the interpretation of PTH assays, including the two-site immunometric assays, which measure intact PTH (iPTH). Refinements in PTH assays have demonstrated that these “intact” PTH assays also measure some large fragments of PTH, which are truncated at the N-terminus and may have important biologic activity. Although more specific assays for so-called bioactive PTH have been developed that exclude these fragments from measurement, work continues to define the clinical utility of such more specific assays.²⁰⁻²² It is hoped that continued efforts will lead to improved standardization between different PTH assays from various laboratories and various manufacturers of assay reagents.¹⁸ With existing intact PTH assays (upper limit of the reference range, approximately 60 pg/ml), only values at the extremes are useful in the noninvasive diagnosis of renal osteodystrophy. In dialysis patients, iPTH levels above approximately 600 pg/ml are characteristic of patients with osteitis fibrosa. It is well accepted that there is an element of skeletal resistance to PTH in patients with CKD; therefore, supranormal levels of PTH appear to be required to maintain normal bone turnover. Serial measurements of PTH are useful in the initial evaluation of patients with renal bone disease and are essential during the management of these disorders to assess response to therapy and to avoid overtreatment and undertreatment because either can have detrimental effects on bone histology. There are marked differences between commercial PTH assay results so that precise recommendations of desired ranges cannot reliably be provided.²³

Vitamin D Metabolites

The levels of calcitriol in patients with CKD are not helpful in differentiating the histologic lesions of renal osteodystrophy. Measurements of calcitriol are not used routinely for diagnostic purposes unless extrarenal production of this metabolite is suspected, as in granulomatous disorders (see Chapter 10).

Vitamin D deficiency in CKD rarely results in osteomalacia in the United States and Europe but may contribute to hyperparathyroidism. In patients with CKD with proteinuria, there is loss of vitamin D-binding protein in the urine, which may result in decreased levels of 25-hydroxyvitamin D. Vitamin D deficiency may be encountered in patients with limited sun exposure, in those with intestinal malabsorption or malnutrition, and in susceptible racial groups, particularly Indo-Asians. Assessment of vitamin D nutrition is by measurement of serum 25-hydroxyvitamin D₃.

Markers of Bone Formation and Bone Resorption

Levels of circulating alkaline phosphatase offer an approximate index of osteoblast activity in patients with CKD. High levels are

commonly present in hyperparathyroid bone disease. The discriminatory power of alkaline phosphatase measurements is enhanced by measurement of bone-specific alkaline phosphatase isoenzyme and in particular in conjunction with PTH values. Serial measurements of alkaline phosphatase may be useful in assessing the progression of bone disease. Osteocalcin is another marker of osteoblastic activity, but it is not superior to alkaline phosphatase. Tartrate-resistant acid phosphatase and collagen degradation products are both markers of osteoclastic activity but are considered investigational at present.

Radiology of the Skeleton

Routine x-ray examination of the skeleton is relatively insensitive for the diagnosis of renal osteodystrophy, and radiographs can appear virtually normal in patients with severe histologic evidence of renal bone disease. However, subperiosteal erosions are often present in severe secondary hyperparathyroidism, detected in the hands (Fig. 81.9), clavicles, and pelvis. Skull radiographs may show focal radiolucencies and a ground-glass appearance, known as “pepper pot” skull. Osteosclerosis of the vertebrae is responsible for the “rugger-jersey” appearance of the spine (Fig. 81.10). Very rarely, brown tumors, focal collections of giant cells and typical of severe hyperparathyroidism, are seen as well-demarcated radiolucent zones in long bones, clavicles, and digits. They may be confused with osteolytic metastases. Looser zones or pseudofractures are characteristic of osteomalacia. Routine skeletal radiographs are not indicated unless there are symptoms.

Measurements of Bone Density

Dual-energy x-ray absorptiometry is widely used to assess bone density. However, there is no clear utility for this technique in the assessment of renal bone disease (see later discussion) because bone density measurements do not correlate with bone histology in renal bone disease. Vascular and soft tissue calcifications may contribute to errors in bone density measurements.

Bone Biopsy

Biopsy of bone and the microscopic analysis of undercalcified sections after double tetracycline labeling provide definitive and

Figure 81.9 Subperiosteal erosions in hyperparathyroidism. Severe subperiosteal erosions as a manifestation of hyperparathyroidism (arrows). The extensive scalloped appearance of the middle phalanx on the left (arrowheads) represents a small brown tumor.

Figure 81.10 “Rugger-jersey spine” in hyperparathyroidism. Vertebral bodies show the increased density of the ground plates and central radiolucency, which gives the appearance of a rugger jersey.

quantitative diagnosis of renal bone disease.²⁴ To standardize reports on bone histology, the Kidney Disease: Improving Global Outcomes (KDIGO) CKD-MBD work group initialized the TMV classification, an assessment of turnover (T), mineralization (M), and bone volume (V).¹ Bone mineralization is assessed by the administration of two different tetracyclines spaced apart (e.g., tetracycline 500 mg three times daily for 2 days followed by a 10-day interval, then demeclocycline 300 mg three times daily for 3 days) and biopsy 4 days later; the quantitation of bone mineralization rate is achieved by measuring the distance between the two fluorescent tetracycline bands.

Bone biopsy is not routinely performed in clinical practice because of the invasive nature of the procedure. Although non-invasive testing is useful to distinguish normal from high bone turnover, there is considerable overlap, and therefore biopsy might be required for definitive diagnosis when biochemistry is not conclusive (e.g., PTH in recommended range but bone alkaline phosphatase elevated, hypercalcemia with PTH only modestly elevated, or bone pain).

Osteitis fibrosa (hyperparathyroid bone disease) is characterized by increased bone turnover, increased number and activity of osteoblasts and osteoclasts, and variable amounts of peritrabecular fibrosis (Fig. 81.11A). Osteoid may be increased but usually has a woven pattern distinct from the normal lamellar appearance. Osteomalacia is characterized by increased osteoid seam width, increase in the trabecular surface covered with osteoid, and decreased bone mineralization as assessed by tetracycline labeling (Fig. 81.11B). The presence of aluminum can be detected on the mineralization front by specific staining (Fig. 81.11C). Aluminum-related bone disease is defined by aluminum staining exceeding 15% of the trabecular surface and a bone formation rate of less than 220 mm² per day. Features of osteitis fibrosa may occur together with features of osteomalacia; the combination is termed mixed renal osteodystrophy.

TREATMENT OF HIGH-TURNOVER BONE DISEASE

Prevention is the primary goal in the management of renal osteodystrophy. Therapy for hyperparathyroidism should ideally be

Figure 81.11 Bone histology in renal osteodystrophy. **A**, Osteitis fibrosa: characteristic manifestations of severe hyperparathyroidism with increased osteoclast and osteoblast activity and peritrabecular fibrosis. **B**, Osteomalacia: marked excess of unmineralized osteoid stained red (arrowhead) surrounding the mineralized bone stained black (arrow). **C**, Aluminum bone disease: specific red staining shows the deposition of aluminum at the mineralization front (arrow).

initiated in CKD stage 3 so that parathyroid gland hyperplasia can be prevented. Because renal osteodystrophy is usually asymptomatic early in the course of CKD, attention is often not paid to secondary hyperparathyroidism. By the time CKD is advanced, patients may have already developed significant skeletal abnormalities or nodular parathyroid hyperplasia, and more aggressive therapy is required to prevent the long-term consequences of renal bone disease. The successful approach to the prevention and management of this disorder involves the integration of a variety of measures directed toward the suppression of PTH secretion and the prevention of parathyroid hyperplasia.

Prevention of Hypocalcemia

Hypocalcemia, if present, should be corrected because it is a potent stimulus for PTH secretion. In patients with hypoalbuminemia, free calcium should be measured. The initial approach to therapy for hypocalcemia in mild to moderate CKD is the administration of calcium supplements such as calcium carbonate, taken between meals with increasing doses as required.

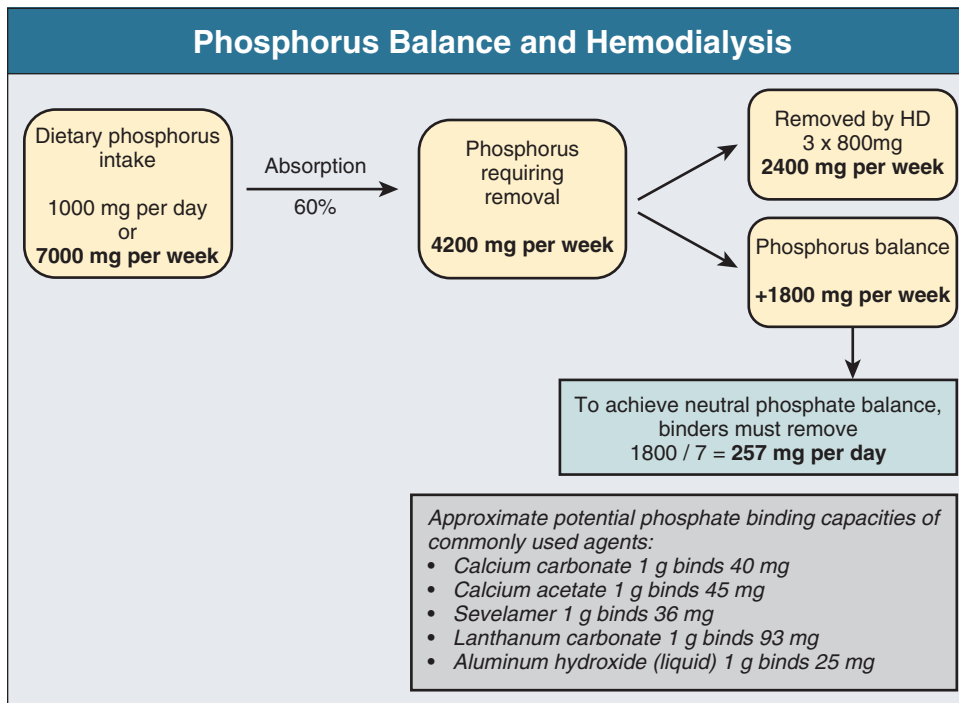

Figure 81.12 Phosphate balance and phosphate binders used in hemodialysis patients.

Assessment of vitamin D status should be undertaken by measurement of 25-hydroxyvitamin D, and this should be corrected if it is below 30 ng/ml. Assessment of efficacy of therapy is by follow-up determinations of serum calcium and PTH. Adjunctive therapy with active vitamin D sterols should be considered if hyperparathyroidism or hypocalcemia persists. In patients with ESRD, active vitamin D sterols are often required. In dialysis patients, the goal is to achieve levels of iPTH that are approximately two to nine times above the upper limit of the assay used.²⁵ Also, iPTH trends over time should be closely monitored. In CKD stages 3 to 5, progressive rises of iPTH above the normal range should be abrogated by correction of hypocalcemia, vitamin D deficiency, and hyperphosphatemia.

Control of Phosphate

Control of phosphate is the cornerstone of effective management of secondary hyperparathyroidism. In mild to moderate CKD, a normal serum phosphate concentration does not necessarily indicate normal parathyroid status, and except for the late stages of CKD, normophosphatemia may be maintained at the expense of elevated serum PTH. Therefore, efforts to control phosphate, including dietary phosphate restriction and the use of phosphate binders, should not be delayed until frank hyperphosphatemia develops.

Dietary Phosphate Restriction

Dietary phosphate intake should already be restricted in CKD stage 2 or 3. In experimental animals with mild CKD, dietary phosphate restriction can prevent excessive PTH synthesis and secretion, as well as parathyroid cell proliferation, independently of changes in serum calcium and calcitriol concentrations. The input of a dietitian is essential. Protein restriction and avoidance of dairy products are the mainstays of the regimen. In addition to reducing CKD progression, phosphate-protein restriction has been shown to increase the serum levels of calcitriol in patients with mild to moderate CKD. Restriction of phosphate by severe

dietary protein restriction should be avoided because it may lead to protein-calorie malnutrition. Restriction of the daily dietary protein intake to 0.8 g/kg should be sufficient to provide phosphate restriction without the risk for malnutrition.

Phosphate Binders

Whereas dietary phosphate restriction is usually sufficient in early CKD, the control of phosphate becomes more difficult as renal function deteriorates. It then becomes necessary to also use agents that bind ingested phosphate in the intestinal lumen to limit its absorption. Compounds used for this purpose include aluminum hydroxide, calcium-containing antacids, magnesium salts, and, in recent years, non-calcium-containing, non-aluminum-containing phosphate binders (Fig. 81.12).

Aluminum-containing antacids are effective phosphate binders, but in patients with CKD, their use can no longer be recommended because of the risk for aluminum toxicity. There are certain circumstances that limit the use of calcium-containing phosphate binders, such as hypercalcemia, extensive vascular calcification, and calciphylaxis. In such cases, aluminum-containing antacids may be used for a short period, but the dose should be restricted to no more than 40 to 45 mg/kg per day, and frequent reassessments should be made to institute alternative therapy as soon as possible. Ingestion of aluminum-containing antacids together with foods containing citric acid (such as fruit juices and foods with sodium, calcium, or potassium citrate) may significantly increase aluminum absorption and therefore should be avoided.

Calcium carbonate or calcium acetate taken with meals effectively binds phosphates and limits their absorption. They are effective phosphate binders in 60% to 70% of patients on hemodialysis. The doses required to prevent hyperphosphatemia may vary according to the patient's compliance with dietary phosphate restriction as well as the CKD stage. Hypercalcemia is the major potentially serious side effect. Calcium citrate potentiates aluminum uptake and should be avoided in CKD. Current recommendations are to limit the ingestion of elementary calcium to 1500 mg/day.

Magnesium salts are also effective phosphate binders for patients who become hypercalcemic with calcium-containing phosphate binders, but they should be administered with caution in CKD patients not on dialysis because hypermagnesemia may have serious adverse effects. In patients on dialysis, magnesium carbonate (200 to 500 mg elemental magnesium per day) has been used successfully, with prevention of hypermagnesemia through a reduction in dialysate magnesium concentration. The use of magnesium carbonate also allows reduction of the dose of calcium carbonate required by about half, but its use is frequently complicated by diarrhea.

The risks for hypercalcemia because of the high calcium load of calcium-containing phosphate binders can be prevented by the use of nonabsorbable polymers. Sevelamer hydrochloride in a dose range of 2.4 to 4.8 g daily provides effective phosphate control without hypercalcemia²⁶ and also produces a significant reduction in total and low-density lipoprotein cholesterol. Agents such as sevelamer may offer great advantage over calcium-containing phosphate binders in terms of limiting the calcium load, although they are significantly more expensive. Studies have suggested that the use of sevelamer is associated with decreased progression of vascular calcification.²⁷ At present, sevelamer hydrochloride is being replaced by sevelamer carbonate, which has similar properties.²⁸ Sevelamer may be combined with both calcium- and magnesium-containing phosphate binders if necessary. Lanthanum carbonate also is an effective phosphate binder²⁹ but is expensive. No significant toxicity has been observed, although some lanthanum appears to accumulate in bone and liver.³⁰

Use of Vitamin D Metabolites

Calcitriol and other 1 α -hydroxylated vitamin D sterols, such as 1 α -hydroxyvitamin D₃ (alfacalcidol), 1 α -hydroxyvitamin D₂ (doxercalciferol), and 19-nor-1 α ,25-dihydroxyvitamin D₂ (paricalcitol), are effective in the control of secondary hyperparathyroidism. Calcitriol lowers PTH levels and improves bone histology. In patients with very high levels of PTH and markedly enlarged glands with severe nodular hyperplasia, the effectiveness of vitamin D metabolites may be limited because the levels of vitamin D receptor are low in such tissue. Accordingly, it would appear rational to initiate treatment of secondary hyperparathyroidism with vitamin D metabolites early in CKD when the parathyroid glands are more sensitive to such therapy and thereby prevent the progression to a refractory stage. A beneficial effect of vitamin D metabolite therapy in the treatment of secondary hyperparathyroidism in patients with mild to moderate CKD has been shown, but the concern with initiation of vitamin D therapy at this stage of CKD is acceleration of the progression of renal disease should hypercalcemia occur. Because of the effect of calcitriol to increase intestinal phosphate absorption, hyperphosphatemia and elevations in calcium-phosphate product may predispose patients to the development of metastatic calcification; however, it appears that doses of 1 α -hydroxyvitamin D₃ or calcitriol up to 0.5 μ g/day are not commonly associated with hypercalcemia, hyperphosphatemia, or worsening renal insufficiency. Another concern with the use of vitamin D metabolites before dialysis is that oversuppression of hyperparathyroidism may increase the risk for adynamic bone. Accordingly, vitamin D therapy should be monitored carefully and should not be instituted without documentation of hyperparathyroidism, correction of 25-hydroxyvitamin D deficiency, and prior control of serum phosphate.

In patients with ESRD, indications for therapy with vitamin D metabolites are better defined; however, hypercalcemia and aggravation of hyperphosphatemia are frequent complications of therapy. Vitamin D metabolites are increasingly used as oral or intravenous pulses given intermittently (e.g., three times weekly) rather than as continuous oral therapy. In recent years, analogues of calcitriol that have less calcemic activity than the parent compound and yet retain the ability to suppress PTH release *in vivo* have been developed. Such analogues of vitamin D studied in patients with ESRD are 22-oxacalcitriol (OCT), 1 α -hydroxyvitamin D₂, and 19-nor-1 α ,25-dihydroxyvitamin D₂ (paricalcitol).³¹⁻³³ Direct comparisons between these compounds are not available. It is likely that a wider therapeutic window may be offered by these analogues. Several studies have suggested that there may be a survival advantage associated with active vitamin D administration in patients with CKD as well as with ESRD.^{34,35}

Role of Calcimimetics

An additional approach to the treatment of hyperparathyroidism in ESRD is the use of a calcimimetic agent, such as cinacalcet, which targets the calcium-sensing receptor and increases its sensitivity to calcium. In dialysis patients, cinacalcet results in a significant fall in PTH levels and when administered daily can facilitate the control of hyperparathyroidism. As illustrated in Figure 81.13, the addition of cinacalcet to standard therapy in patients with iPTH serum levels exceeding 300 pg/ml while receiving standard therapy allowed significantly more dialysis patients to achieve Kidney Disease Outcomes Quality Initiative (KDOQI) practice guideline targets for calcium, phosphate, and iPTH.³⁶ Cinacalcet is especially useful in patients with marginal or frank hypercalcemia or with hyperphosphatemia and can be used in conjunction with other therapies. Studies investigating the effect of cinacalcet on progression of vascular calcification and survival in dialysis patients with hyperparathyroidism are ongoing. In CKD patients not on dialysis, the use of calcimimetics is accompanied by significant phosphate retention and is currently not recommended.

Role of Parathyroidectomy

Although the strategies discussed previously are effective for the control of hyperparathyroidism in many patients, there are occasions when these steps fail or are contraindicated and surgical removal of the parathyroids should be considered (Fig. 81.14). Parathyroidectomy is indicated for patients with severe hyperparathyroidism that cannot be controlled medically (phosphate binders, vitamin D sterols, or calcimimetic). Severe hyperphosphatemia in these patients precludes the use of vitamin D metabolites because of the risk for metastatic calcification. Some control of iPTH levels may be obtained with calcimimetics, but even these compounds may fail in severe hyperparathyroidism because of downregulated calcium-sensing receptors in the parathyroid glands. Some patients with severe hyperparathyroidism may become hypercalcemic in the absence of calcitriol therapy; consequently, calcitriol and calcium-containing phosphate binders cannot be administered. In this circumstance, calcimimetic and non-calcium-containing phosphate binders should be administered. It is important to be certain that hypercalcemia represents severe hyperparathyroidism and is not caused by adynamic bone or other disease. For hypercalcemia to occur because of hyperparathyroidism in CKD, the levels of iPTH generally

Figure 81.13 Cinacalcet hydrochloride (dark blue line) added to standard therapy (light blue line) facilitates the achievement of the Kidney Disease Outcomes Quality Initiative (KDOQI) clinical practice guidelines. KDOQI target ranges are indicated by the shaded green areas. PTH, parathyroid hormone. (Modified from reference 36.)

Indications for Parathyroidectomy

Severe hyperparathyroidism
With persistent hyperphosphatemia
Unresponsive to calcitriol and calcium
With hypercalcemia
In renal transplantation candidate
With evidence of metastatic calcification
Calciophylaxis with evidence of hyperparathyroidism
Severe pruritus, only if additional evidence of hyperparathyroidism

Figure 81.14 Indications for parathyroidectomy.

exceed 1000 pg/ml, and bone-specific alkaline phosphatase is usually elevated. Surgical parathyroidectomy might also be considered in patients with very severe hyperparathyroidism who may receive a renal transplant in the near future, particularly if they are female and have significant osteopenia. Parathyroidectomy in these cases can help avoid post-transplantation hypercalcemia and hypophosphatemia (due to PTH-induced phosphaturia) as well as osteopenia. By avoiding hypercalcemia, this may lead to improved graft function and possibly to less intragraft calcification. Parathyroidectomy might also be con-

sidered in patients with severe hyperparathyroidism who have evidence of metastatic calcification. The development of calciophylaxis is an urgent indication for parathyroidectomy if PTH levels are elevated (see Chapter 84). Before parathyroidectomy, consideration should also be given to the possibility of coexisting aluminum accumulation, using deferoxamine testing and bone biopsy if necessary, because this might predispose to osteomalacia after parathyroidectomy.

The choice of surgical procedure for parathyroidectomy has been controversial. The most commonly used procedures are subtotal removal of the parathyroids and total removal of the parathyroids with reimplantation of parathyroid tissue in the forearm. Recurrence of hyperparathyroidism occurs in about 10% of patients. Total parathyroidectomy alone is less commonly performed; although this is an appropriate procedure for patients remaining on dialysis, there is concern that hypoparathyroidism after a renal transplantation may be a disadvantage of this approach if there is no residual parathyroid tissue. Unregulated tumor-like growth of parathyroid tissue implants has been described and may be related to the monoclonal nature of the nodular hyperplasia of severe hyperparathyroidism. Total parathyroidectomy with forearm implantation (our preference) or subtotal parathyroidectomy in the neck, marking remaining tissue with clips, may be performed.

Figure 81.15 Treatment of renal osteodystrophy at various stages of renal insufficiency. GFR, glomerular filtration rate; PTH, parathyroid hormone. Note: PTH target range in this figure is based on the older KDOQI recommendation of 150–300 pg/ml, whereas the newer KDIGO target range is about 120 to about 540 pg/ml.

Recurrence of hyperparathyroidism may respond to further medical therapy, but more surgery to remove the forearm implant or further neck exploration to search for additional glands is often necessary.

Synthesis of Therapeutic Strategies

The general recommendations for the prevention and therapy of renal osteodystrophy are summarized in Figure 81.15, in which therapeutic maneuvers are stratified according to the degree of CKD.

Therapy should be initiated if possible in stage 2 or 3 CKD (GFR, 30 to 90 ml/min), and dietary phosphate intake should be restricted once patients enter CKD stage 3. Levels of iPTH should be measured; if elevated above the normal range, the levels of 25-hydroxyvitamin D should be measured and corrected if less than 30 ng/ml. If hyperparathyroidism persists, calcium-based phosphate binders, 1 to 3 g/day administered with meals, should be initiated and the dose adjusted as required to achieve control of hyperparathyroidism.

As CKD progresses within stage 3, dietary phosphate restriction should be continued or intensified, and the doses of calcium-containing phosphate binders should be adjusted on the basis of serial measurements of iPTH, with careful attention to avoid hypercalcemia or excessive calcium load. Acidosis, if present, should be treated with oral sodium bicarbonate because persistent acidosis has deleterious effects on the skeleton. The additional sodium load may require further salt restriction or increases in diuretics. Aluminum-based phosphate binders should be avoided. If hyperparathyroidism (iPTH >100 pg/ml) persists despite these measures, consideration should be given to the addition of calcitriol (0.25 to 0.5 µg/day), vitamin D analogues, or vitamin D prohormones to the regimen. Such therapy should

be monitored carefully to avoid hypercalcemia and acceleration of progression of renal failure.

In CKD stages 4 and 5, the preceding therapies may need to be intensified, and larger amounts of phosphate binders may be required to avoid hyperphosphatemia. The use of aluminum-containing phosphate binders is particularly undesirable at this stage in view of the increased risk for aluminum accumulation with worsening renal function. In patients on dialysis, calcitriol therapy can be intensified, with attention to the serum levels of calcium and phosphate and monitoring of iPTH levels. In CKD stage 5, iPTH levels should be maintained approximately two to nine times above the upper limit of the assay used to maintain normal bone turnover. Calcitriol may be administered orally either daily or intermittently (pulse therapy) or administered intravenously to patients on hemodialysis. During therapy with calcitriol, it is imperative to ensure that serum phosphate remains controlled and that elevations of serum calcium do not occur to prevent metastatic calcification. Vitamin D analogues, which are less calcemic and phosphatemic than calcitriol and yet retain the ability to suppress the levels of PTH, may be useful. The calcimimetic cinacalcet provides additional effective control of hyperparathyroidism in patients with ESRD and may be used alone or in combination with the other strategies if iPTH levels do not fall into the target range. Parathyroidectomy needs to be considered in selected circumstances. Bone biopsy may be indicated in selected patients, particularly if aluminum overload is suspected. Aluminum overload may require chelation therapy with deferoxamine in selected circumstances, especially if it is symptomatic, but in most cases, the prevention of further aluminum exposure is sufficient to allow a gradual reduction in the serum levels of aluminum. During therapy with potent vitamin D metabolites, attention should be given to the dialysate calcium concentrations because high concentrations may aggravate

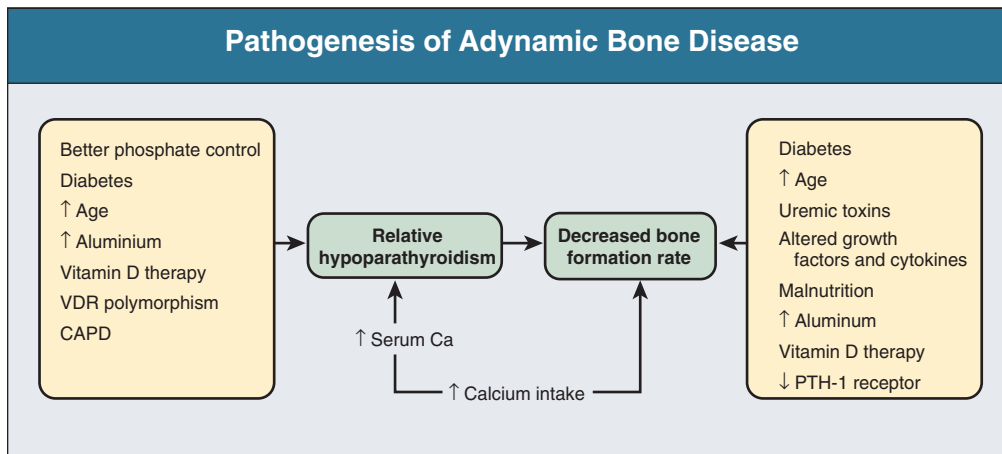

Figure 81.16 Pathogenesis of adynamic bone disease. CAPD, continuous ambulatory peritoneal dialysis; PTH, parathyroid hormone; VDR, vitamin D receptor. (Modified from reference 59.)

hypercalcemia. However, the increasingly frequent use of lower dialysate calcium levels, such as 1.25 mmol/l, requires careful monitoring of the patient to ensure compliance with calcium-containing phosphate binders and vitamin D metabolites to avoid progressive negative calcium balance. Dialysate calcium should not be taken outside the range of 1.25 to 1.75 mmol/l and, when possible, should be individually prescribed.

LOW-TURNOVER RENAL OSTEOPATHY

Adynamic bone disease (ABD) describes the morphologic consequences of low-turnover osteopathy in CKD. As CKD progresses, high-turnover renal osteodystrophy initially develops as an adaptive response to counteract the increasing skeletal PTH resistance and phosphate overload. ABD probably results from too rigorous suppression of this adaptive response. ABD is increasingly important in CKD-MBD because of the high percentage of affected individuals (>40% in CKD stage 5) and because of its association with cardiovascular calcification and mortality.^{37,38} Furthermore, fracture incidence is estimated to be twice as high in individuals with low than in those with high bone turnover. The ABD prevalence is markedly increasing in bone biopsy registries of dialysis patients, which may relate to the increasing prevalence of its central risk factors, namely, advanced age and diabetes mellitus. Peritoneal dialysis also represents a risk factor, possibly because of a continuous exposure of the patient to high dialysate calcium as opposed to hemodialysis, in which calcium exposure is cyclic.

Pathogenesis of Adynamic Bone Disease

As pointed out earlier, the bone develops a relative resistance of the PTH-1 receptor to its ligand PTH as CKD progresses. Therefore, PTH levels above the normal range are required to maintain adequate bone turnover. Unfortunately, there are no definite ranges of elevated PTH levels that can reliably differentiate an adaptive response (normal bone turnover) from a maladaptive response (increased bone turnover) because PTH resistance individually varies and because it depends on the stage of CKD. Accordingly, ABD is a consequence of inadequately low PTH levels, which cause suppression or cessation of both osteoblast and osteoclast activities, resulting in a reduced bone formation rate and low bone mass. Iatrogenic oversuppression of PTH in CKD mostly results from high-dose active vitamin D metabolite treatment, from calcium loading (high doses of calcium-

containing phosphate binders, high dialysate calcium concentration), or after parathyroidectomy. The effects of intensified calcimimetic treatment on bone turnover have not yet been systematically evaluated. Finally, diabetes, uremic toxins, malnutrition, and a disproportionate appearance of C-terminal PTH fragments may be additional factors favoring a state of low bone turnover (Fig. 81.16).

Diagnosis and Differential Diagnosis

Serum Biochemistry

Low iPTH levels (<100 pg/ml) are almost always indicative of low bone turnover in CKD stage 5. However, histologically proven ABD may occur in many dialysis patients with iPTH levels of up to 300 pg/ml and, in exceptions, of up to 600 pg/ml.^{39,40} Therefore, PTH levels alone are not a sensitive biomarker of ABD. Serum levels or activities of alkaline phosphatase or bone-specific alkaline phosphatase are usually normal or low; downward trends may indicate the development of ABD. Serum calcium and phosphate can be normal or elevated, dependent on the choices of co-treatment (phosphate binders, vitamin D metabolites) and on the nutritional status. Particularly in instances of calcium and phosphate loading, hypercalcemia and hyperphosphatemia may be pronounced because adynamic bone is no more able to buffer calcium and phosphate loads by osseous deposition (Fig. 81.17).

In CKD stages 3 and 4, there are uncertainties with regard to the diagnosis of ABD and its clinical consequences. It is unclear which PTH levels are required to maintain adequate bone turnover in these stages. It seems reasonable to correct vitamin D deficiency, hyperphosphatemia, and hypocalcemia when PTH levels start to rise, but beyond that, no firm recommendations can be given at this time.

Bone Biopsy

The gold standard for diagnosis of ABD is bone biopsy. According to the TMV classification (see earlier discussion), ABD is characterized by low turnover, normal (or high secondary) mineralization, and low bone (osteoid) volume. The individual indication to perform bone biopsy should be considered in symptomatic subjects on the basis of inconsistencies of biochemical parameters associated with unexplained fractures, bone pain, progressive extraosseous calcifications, or hypercalcemia. The KDIGO initiative currently investigates 800 or more bone biopsy and concomitant serum samples to identify biomarker

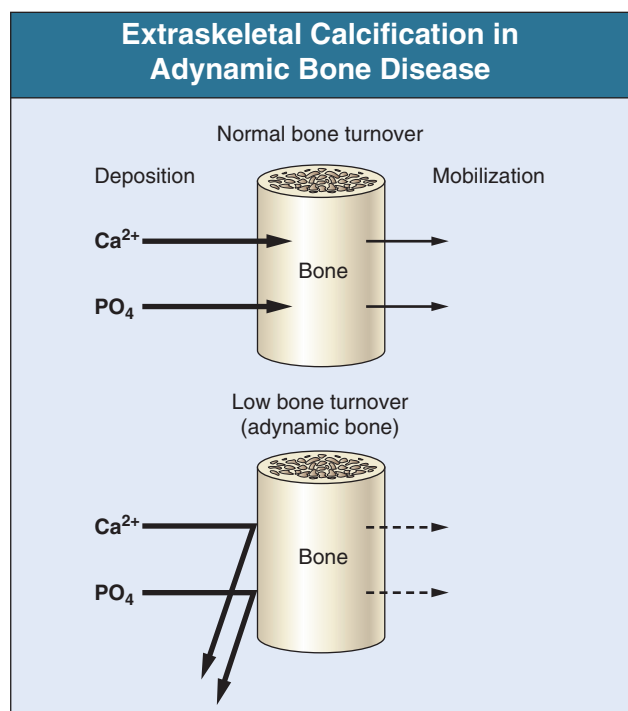

Figure 81.17 Bone turnover in adynamic bone disease. Reduced bone turnover leads to increased extraskeletal calcification.

patterns that may allow noninvasive testing of bone turnover status. Aluminum toxicity is a relevant differential diagnosis versus ABD. Thus, if the patient's history suggests significant aluminum exposure, aluminum bone deposition should be excluded by specific staining.

Radiology and Measurements of Bone Density

There are no typical features of ABD in conventional bone radiographs and in dual-energy x-ray absorptiometry. In the latter, bone density may be low, normal, or high, depending on the primary or secondary mineralization state, but it never reflects the actual turnover and is therefore not a helpful diagnostic test (Fig. 81.18). A very high cardiovascular calcification burden on conventional radiographs may raise the suspicion of a low bone turnover state if accompanying biochemical parameters are compatible with this diagnosis. Biopsy-proven ABD is associated with the highest magnitude of vascular calcification in dialysis patients.³⁸

Treatment of Adynamic Bone Disease

The key therapeutic approaches in the treatment of ABD are to avoid PTH overexpression and to restore adequate PTH levels, without triggering the progressive development of secondary hyperparathyroidism. Such a stepwise treatment approach may include reduction or withdrawal of active vitamin D metabolites, reduction or withdrawal of calcium-containing phosphate binders, and reduction of the dialysate calcium concentration (usually to 1.25 mmol/l). Any aluminum should be withdrawn. After these interventions, biochemical parameters (PTH, calcium, phosphate, perhaps alkaline phosphatases) should be monitored more frequently than usual.

The best study data on this issue are available from studies comparing calcium-containing versus non-calcium-containing phosphate binders in dialysis patients.^{39,41} In comparing baseline

with follow-up bone biopsies in such cohorts, the administration of calcium-containing phosphate binders was associated with a higher percentage of individuals who developed ABD. This development was associated with a fall in serum PTH due to the higher calcium load. In an observational study, it was also shown that high-dose calcium-containing phosphate binder intake was associated with both low bone turnover and increased aortic calcification.⁴² Other therapeutic approaches to ABD have not been systematically studied. They include optimized diabetes control, a change from peritoneal dialysis to hemodialysis to facilitate a more flexible dialysate calcium prescription, the administration of recombinant PTH (e.g., for patients after total parathyroidectomy), and calcilytics.⁴³ At present, many patients with ABD remain refractory to treatment.

OSTEOPOROSIS IN CHRONIC KIDNEY DISEASE

Whereas abnormal bone is common and fracture risk is increased in CKD patients, the relative contribution of classic osteoporosis (as defined by World Health Organization criteria) to the CKD-MBD complex is not well defined. Data from studies of antiosteoporosis agents are available only for patients in CKD stages 1 to 3. Nevertheless, postmenopausal women and elderly men nowadays are highly prevalent in late-stage CKD populations, and it is thus likely that classic osteoporosis also contributes to their bone disease.

Pathogenesis of Osteoporosis in Chronic Kidney Disease

Osteoporosis may be associated with low, normal, or high bone turnover and is characterized by thin and disconnected trabeculae and the loss of the plate-like bone structure. Many patients with CKD have abnormal mineralization and increased osteoid, which is quite untypical for osteoporosis. Typical pathogenetic factors of osteoporosis including hypoestrogenemia, immobilization, and corticosteroid use are frequent in CKD patients, although some postmenopausal women in late-stage CKD may have relatively normal estrogen levels. However, the sum of CKD-MBD-related biochemical disturbances probably represents the decisive factors as to which bone phenotype predominates. Secondary hyperparathyroidism, relative hypoparathyroidism (as in ABD), and 25-hydroxyvitamin D as well as 1,25-dihydroxyvitamin D deficiencies may dominate and "overrule" the bone phenotype of osteoporosis even if classic risk factors are present.

Diagnosis and Differential Diagnosis

In patients with advanced CKD, bone turnover biomarkers and measurements of bone mineral density by dual-energy x-ray absorptiometry are useless tools (Fig. 81.18) in the differential diagnosis of classic osteoporosis from other CKD-MBD-related bone disease. Assays for biomarkers such as β -crosslaps (C-terminal cross-linked, CTX; marker of bone collagen degradation), procollagen type I N-terminal propeptide (PINP; marker of bone collagen synthesis), and tartrate-resistant alkaline phosphatase 5b (TRAP5b; marker of osteoclast activity) are insufficiently validated in CKD patients, and low bone mineral density can be found in CKD-MBD-induced high-turnover bone disease, ABD, and osteomalacia (Fig. 81.18). Further, bone mineral density does not predict fracture risk in CKD patients

The Value of Bone Density Measurements in the Assessment of CKD-Related Bone Disease					
Clinical Situation:	Normal bone	Osteoporosis	Osteomalacia	Adynamic Bone Disease	Secondary Hyperparathyroidism
Bone Composition:	Normal bone mass	Low bone mass	Normal bone mass	Low bone mass	Normal or increased bone mass
	Normal primary mineralisation	Normal primary mineralisation	Abnormal primary mineralisation	High secondary mineralisation	Decreased secondary mineralisation
Measured BMD:	1.250 g/cm ²	0.625 g/cm ²	0.625 g/cm ²	0.625 g/cm ²	0.625 g/cm ²
Densitometry Report:	Normal BMD	"Osteoporosis"			
NOTES: Right column needs to be higher than the others

as it does in the general population, implying that abnormal bone quality rather than density is the major disturbance in such patients. The only reliable methodology to diagnose osteoporosis and to discriminate it from other bone manifestations in CKD patients is bone biopsy. In a large bone biopsy study including 1429 samples from dialysis patients, osteoporosis was diagnosed in 52% of individuals, and 49% of them also had ABD.⁴⁴ These percentages may be quite different in patients in earlier CKD stages, but there are no systematic data available on such cohorts.

Treatment of Osteoporosis in Chronic Kidney Disease

Post hoc analyses of large prospective treatment studies using antiosteoporotic medications demonstrated that it seems safe and efficacious to treat postmenopausal women in stages CKD 1 to 3 if they have a high risk of fractures (according to World Health Organization criteria) and no features of CKD-MBD.⁴⁵⁻⁴⁸ In such populations, bisphosphonates, raloxifene, and teriparatide appear to be feasible therapeutic options. In contrast, for patients in CKD stages 3 to 5 with features of CKD-MBD, there are no data available on the safety and efficacy of any of these antiosteoporotic medications. In CKD patients with ABD, bisphosphonates may aggravate osteoclast paralysis. In CKD patients with secondary hyperparathyroidism, bisphosphonates may upregulate PTH secretion. None of these antiosteoporotic compounds can thus be recommended in patients with CKD-MBD to date, unless bone biopsy proves the exclusive presence of osteoporosis.

β_2 -MICROGLOBULIN-DERIVED AMYLOID

β_2 -Microglobulin-derived ($\text{A}\beta_2\text{M}$) amyloidosis, also termed dialysis-associated amyloidosis, exclusively affects patients with stage 5 CKD. It is a systemic amyloidosis. Clinical manifestations are largely confined to the musculoskeletal system. In recent years, the disease has become notably infrequent.

Pathogenesis

Fibrils of $\text{A}\beta_2\text{M}$ amyloid are derived from the circulating precursor protein β_2 -microglobulin, the nonvariable light chain of the HLA class I complex. The pathogenesis appears to involve three events: (1) pronounced renal retention of β_2 -microglobulin (11.8 kD), leading to plasma levels that can be elevated up to 60-fold in dialysis patients⁴⁹; (2) modifications of the β_2 -microglobulin molecule that render it more amyloidogenic, such as limited proteolysis or the formation of different sugar-protein cross-links^{50,51}; and (3) local factors that contribute to and determine the particular spatial localization of the amyloidosis.

Epidemiology

Histologic studies from the 1990s observed amyloid deposits in 100% of dialysis patients treated for more than 13 years.⁵² Most amyloid deposits never cause clinical problems. Main risk factors for $\text{A}\beta_2\text{M}$ amyloid deposition are age at onset of renal replacement therapy and the duration of (nontransplant) renal replacement therapy.^{49,50} $\text{A}\beta_2\text{M}$ amyloid-related symptoms nowadays are largely confined to patients who have been dialyzed for more than 15 years.

Clinical Manifestations and Diagnosis

$\text{A}\beta_2\text{M}$ amyloidosis mainly is manifested at osteoarticular sites, particularly synovial membranes; visceral manifestations are rare.^{49,50} Carpal tunnel syndrome typically worsens at night and during hemodialysis. It is often bilateral and usually requires surgery. Osteoarthropathy of peripheral joints, resulting from amyloid deposition in periarticular bone and the synovial capsule (Fig. 81.19), is characterized by recurrent or persistent arthralgias, stiffness of large and medium-sized joints, and swelling of capsules and adjacent tendons. Recurrent joint effusions and synovitis, often in the shoulders and knees, may occur. The clinical presentation may vary from frank, acute arthritis to slow, progressive destruction of the affected joints. Destructive spondylarthropathy (Fig. 81.20) resulting from $\text{A}\beta_2\text{M}$ amyloidosis can be manifested as asymptomatic deposits, radiculopathy, stiffness, "mechanical

Figure 81.19 $A\beta_2M$ amyloid deposition in the femoral head. Post-mortem specimen from a long-term hemodialysis patient. Two large lesions (arrowheads), partly filled with grayish amyloid and partly cystic, are noted in the femoral head. Also note the marked thickening of the synovial capsule due to amyloid deposition (arrow).

ache,” and, finally, medullary compression with resulting paraplegia or cauda equina syndrome.^{49,50} Other manifestations include camptodactyly (a flexion deformity resulting in bent fingers that cannot completely extend or straighten) resulting from amyloid deposits along the flexor tendons of the hands (Fig. 81.21). Patients undergoing dialysis can also have subcutaneous tumorous deposits of $A\beta_2M$ amyloid; however, diffuse infiltration of the subcutaneous fat or skin has not been observed.

Case reports of clinically relevant organ manifestations are usually in patients treated with hemodialysis for more than 15 years and have described heart failure, odynophagia, intestinal perforation of both small and large bowel, gastrointestinal bleeding and pseudo-obstruction, gastric dilation, paralytic ileus, persistent diarrhea, macroglossia or functional tongue disturbances (abnormal taste, mobility, articulation), ureteral stenosis, and renal calculi.^{49,50}

Diagnosis

Plasma levels of β_2m do not distinguish between patients with the amyloidosis and those without. Ultrasound can detect synovial $A\beta_2M$ amyloidosis as thickening of the joint capsules of the hip and knee, biceps tendons, and rotator cuffs as well as the presence of echogenic structures between muscle groups and joint effusions.⁵⁰ On radiologic examination, affected joints may present with single or multiple juxta-articular, “cystic” (i.e., amyloid-filled) bone radiolucencies (Fig. 81.22; see also Fig. 81.19). Such bone defects are prone to pathologic fractures. Diagnostic criteria for $A\beta_2M$ amyloid-induced cystic bone radiolucencies have been published.⁵³ They include (1) diameter of lesions more than 5 mm in wrists and more than 10 mm in shoulders and hips, (2) normal joint space adjacent to the bone defect, (3) exclusion of small subchondral cysts in the immediate weight-bearing area of the joint and of defects of the “synovial inclusion” type, (4) increase of defect diameter of more than 30% per year, and (5) presence of defects in at least two joints. Scintigraphy, employing either radiolabeled serum amyloid P component or β_2 -microglobulin,⁵⁴ offers more specific detection of amyloid deposits but is not widely available. The definitive diagnosis of $A\beta_2M$ amyloidosis relies on histology. Fat aspiration and rectal biopsy are not helpful in $A\beta_2M$ amyloidosis, but diagnostic material can be obtained from synovial membranes, synovial fluid, or bone lesions.⁴⁹

Figure 81.22 Peripheral bone cystic radiolucencies in $A\beta_2M$ amyloidosis. Radiographic findings in a long-term hemodialysis patient. **A**, Multiple cystic lesions (arrows) are present in the hand bones. **B**, Large cysts (arrows) in the neck of the femur and adjacent pelvic bones. **C** and **D**, Anterior and lateral views of the head of the tibia with two very large, cystic lesions (arrows) resulting in posterior bulging of the tibial plateau.

Treatment and Prevention

Therapy for established $A\beta_2M$ amyloidosis is symptomatic. NSAIDs and physical and surgical measures such as carpal tunnel decompression, endoscopic coracoacromial ligament release, and bone stabilization in areas of cystic destruction are all used.⁴⁹ Although some dialysis modalities allow significant removal of β_2 -microglobulin, there is at present no convincing evidence that this is of therapeutic value in an established $A\beta_2M$ amyloidosis. Renal transplantation is the preferred treatment because it leads to rapid symptomatic improvement and halts further progress of the disease, but it is controversial whether this can actually lead to regression of established $A\beta_2M$ amyloid deposits.

A number of strategies exist for prevention of the clinical manifestations of $A\beta_2M$ amyloidosis.^{49,50} The risk of carpal tunnel syndrome is reduced by 40% to 50% in patients treated with high-flux hemo(dia)filtration⁵⁵ and minimal in patients receiving online hemodiafiltration.⁵⁶ A dramatic reduction in the prevalence of carpal tunnel syndrome occurred in patients dialyzed with ultrapure dialysate.⁵⁷ In another study, an 80% reduction of amyloid signs in a chronic hemodialysis population appeared to relate to dialysate factors such as microbiologic purity and the use of bicarbonate buffer.⁵⁸

Neurologic Complications of Chronic Kidney Disease

Julian Lawrence Seifter, Martin A. Samuels

Disorders of the nervous system are associated with renal disease in patients with systemic disorders (e.g., hypertensive encephalopathy, thrombotic microangiopathies, atheroembolic and atherosclerotic disease, vasculitides), fluid and electrolyte abnormalities, and multisystem disease in the intensive care unit setting and with chronic kidney disease (CKD). Furthermore, patients with CKD are at increased risk of toxin- and pharmacologic agent-induced neurotoxicity. This chapter focuses on the direct neurologic consequences of CKD.

UREMIC ENCEPHALOPATHY

The syndrome of uremic encephalopathy (UE) involves a spectrum of brain abnormalities that may clinically range from nearly imperceptible changes to coma.

Pathogenesis

The brain in CKD has decreased metabolic activity and oxygen consumption.^{1,2} As long as the underlying renal disease has not affected cerebral hemodynamics and responsiveness to carbon dioxide, these functions appear intact, but subtle disturbances have been detected after dialysis.

Many theories support the role of uremic toxins that accumulate in CKD. The balance of excitatory and inhibitory neurotransmitters may be disrupted by organic substances,³ in particular guanidino compounds, which are increased in the cerebrospinal fluid.^{4,5} These compounds antagonize γ -aminobutyric acid (GABA_A) receptors and at the same time have agonistic effects on *N*-methyl-D-aspartate glutamate receptors, leading to enhanced cortical excitability. Asymmetric dimethylarginine,⁶ which is increased in CKD, inhibits endothelial nitric oxide synthase, and levels correlate with cerebrovascular complications in uremia. Disturbances in monoamine metabolism include a depletion of norepinephrine and suppression of central dopamine, which has been linked to the impairment of motor activity in uremic rats. Myoinositol, carnitine, indoxyl sulfate, polyamines, and decreased transport functions and increased permeability of the central nervous system have also been implicated in the neuronal dysfunction of uremia. Metabolites of drugs, including cimetidine and acyclovir, may be increased in uremia because of inhibition of the organic anion transporter (OAT3), and neurotoxic syndromes may result.⁷ Levels of opiates and in particular metabolites of meperidine

increase in plasma because of decreased excretion through cation secretory transport, with subsequent neurotoxicity.

Secondary hyperparathyroidism may also play a role in UE^{8,9} as brain calcium is increased in CKD and calcium transporters within neurons are parathyroid hormone sensitive. Increased cellular calcium may play a role in neuroexcitation.

Appetite regulation is abnormal in uremia (see Chapter 83). A high rate of tryptophan entry across the blood-brain barrier may increase the synthesis of serotonin, a major appetite inhibitor.¹⁰ High levels of cholecystokinin, a powerful anorectic, and low levels of neuropeptide Y, an appetite stimulant, have been observed. Cachexia may result from anorexia, acidosis, and inflammation. Inflammatory cytokines such as leptin, tumor necrosis factor α , and interleukin-1 may signal anorexigenic neuropeptides such as pro-opiomelanocortin and α -melanocyte-stimulating hormone in the arcuate nucleus of the hypothalamus.

Clinical Manifestations

Whereas 20% of patients with acute kidney injury in an intensive care unit setting developed neurologic impairment,¹¹ the syndrome in CKD is more subtle, not correlating closely to the level of uremia.^{1,12} Cross-sectional studies in hemodialysis (HD) patients found cognitive impairment in 30%, with about 10% exhibiting severe impairment. Neurocognitive deficits may have special implications for CKD in early childhood, adversely affecting development of the brain.¹³

UE can be manifested as complex mental changes or motor disturbances (Fig. 82.1). The full-blown syndrome is a risk factor for morbidity and mortality.^{1,2} Mental changes include emotional changes, depression, disturbing and disabling cognitive and memory deficits, and, in the most severe form, a generalized disorder characterized by delirium, psychosis, seizures, coma, and ultimately death. Such advanced UE is usually seen only in patients in whom a decision has been made not to initiate renal replacement therapy (see also Chapter 75). Severe motor symptoms or signs are rare. Depression, anxiety, and even suicide are important underdiagnosed and undertreated aspects of uremia and may be related to metabolic or poor nutritional state and fear of dialysis or death. Other known causes of depression should always be sought.

Stable UE is manifested by fine action tremor, asterixis, and hyperreflexia. Asterixis is characterized by intermittent loss of

Clinical Manifestations of Uremic Encephalopathy	
Early Encephalopathy	Late Encephalopathy
Mental Changes	
Mood swings	Altered cognition and perception
Impaired concentration, loss of recent memory	Illusions, visual hallucinations, agitation, delirium
Insomnia, fatigue, apathy	Stupor, coma
Motor Changes	
Hyper-reflexia	Myoclonus, tetany
Tremor, asterixis	Hemiparesis
Dysarthria, altered gait, clumsiness, unsteadiness	Convulsions

Figure 82.1 Clinical manifestations of uremic encephalopathy (UE).

muscle tone in antigravity muscles. It is distinguished from tremor by the fact that it is not an oscillation but rather an intermittent loss of tone. Myoclonus is also seen in patients with UE. It is similar in timing to asterixis (10 to 100 milliseconds) but is due to activation of antigravity muscles. For this reason, some consider asterixis to be a form of negative myoclonus. The distinction between asterixis and myoclonus is less important than once thought as both or either may be present in many metabolic encephalopathies and some structural brain diseases as well. Asterixis and myoclonus may be elicited with the hands outstretched but may be more sensitively assessed by looking at the protruded tongue or the index finger raised with the hand resting on a firm surface. Asterixis and myoclonus may be seen in patients with renal impairment who have received various drugs (e.g., metoclopramide, phenothiazines, antiepileptic drugs including gabapentin, and opioids, especially meperidine). Metabolic acidosis may also produce an indistinguishable encephalopathy, as can aluminum toxicity. Therefore, before it is considered a clinical feature of advanced uremia requiring renal replacement therapy, a careful search for other causes should be initiated.

Advanced UE is usually characterized by a reduced level of consciousness, anorexia, asterixis, myoclonus, and upper motor neuron signs that result in disturbances of gait and speech.

Diagnosis and Differential Diagnosis

The diagnosis of UE is based on clinical findings and their improvement after adequate therapy (see next section). Lumbar puncture, electroencephalography, and imaging procedures largely serve to exclude other causes in patients in whom the clinical diagnosis is doubtful. In UE, the cerebrospinal fluid is often abnormal, sometimes demonstrating a modest pleocytosis (usually <25 cells/mm³) and increased protein (usually <100 mg/dl). The electroencephalogram is usually abnormal but non-specific. Generalized slowing with an excess of delta and theta waves is found.¹⁴ Brain imaging (Fig. 82.2) usually shows cerebral atrophy and enlargement of the ventricles.

The differential diagnosis of UE is shown in Figure 82.3. Seizure activity may be secondary to UE, hypertensive encephalopathy, cerebral embolism, cerebral venous thrombosis, or electrolyte and acid-base abnormalities. Tetany can develop when treatment involves alkalization of an acidemic patient with renal disease and hypocalcemia.

Figure 82.2 Magnetic resonance imaging (MRI) findings in uremic encephalopathy. Axial T2-weighted MRI (fluid-attenuated inversion recovery) in a 40-year-old woman. The extensive hyperintense lesion involves the cortical and subcortical areas of both occipital lobes and, in a more focal distribution, the basal ganglia and the frontal white matter (arrows). The volume of the affected brain parenchyma is increased. Reversibility of the MRI changes was noted 2 weeks later after the initiation of regular dialysis. (Courtesy A. Thron, Aachen, Germany.)

Treatment

Most nephrologists consider advanced cognitive or memory impairment an indication for initiation of renal replacement therapy. Most of the manifestations of central nervous system involvement are reversible with dialysis within days or weeks, but mild signs of UE may persist. In dialyzed patients with persistent or recurrent symptoms, increasing the delivered dialysis dose may improve clinical findings. Successful renal transplantation usually results in resolution of the UE syndrome within days.

Correction of anemia with recombinant erythropoietin in the dialysis patient to a target hemoglobin level of 11 to 12 g/dl (see Chapter 79) may be associated with improved cognitive function and decreased slowing on the electroencephalogram.¹⁵ Too rapid overcorrection of anemia may be associated with seizures. Similarly, parathyroid hormone suppression with vitamin D analogues and cinacalcet is important given the potential role of parathyroid hormone as neurotoxin (see Chapter 81). Treatment of psychosis in kidney disease must take into account the pharmacokinetics of the specific agent. For example, risperidone may have utility, but dose reduction is necessary because of a prolonged half-life with CKD.

PERIPHERAL NEUROPATHY

Patients with CKD are susceptible to both polyneuropathies and mononeuropathies. The pathophysiologic process of polyneuropathy involves axonal degeneration in a length-dependent fashion. Primary demyelinating neuropathies are rare in the context of CKD except when the renal disease is the result of an illness that also causes demyelination (e.g., multiple myeloma). Mononeuropathies may be due to entrapment with compression of metabolically weakened nerves, particularly in wheelchair-bound or bed-bound patients. Mononeuritis multiplex should

Differential Diagnosis of Uremic Encephalopathy	
Differential Diagnosis	Comment
Hypertensive encephalopathy	
Systemic inflammatory response syndrome (SIRS)	Observed in septic patients
Systemic vasculitis	Vasculitis or lupus with cerebral involvement
Drug-induced neurotoxicity	
Analgesics	Meperidine, codeine, morphine, gabapentin
Antibiotics	High-dose penicillins (may cause seizures), acyclovir, ethambutol (optic nerve damage), erythromycin and aminoglycosides (may cause ototoxicity), nitrofurantoin and isoniazid (peripheral neuropathy)
Psychotropics	Lithium, haloperidol, clonazepam, diazepam, chlorpromazine
Immunosuppressants	Cyclosporine, tacrolimus
Chemotherapeutics	Cisplatin, ifosfamide
Others	High doses loop diuretics (ototoxic), ephedrine, methyl dopa, aluminum
Cerebral atheroembolic disease	Follows recent aortic or cardiac angiography; associated with peripheral manifestations, including lower extremity cyanosis, livedo reticularis, and eosinophilia
Subdural hematoma	
Posterior leukoencephalopathy	Observed particularly following renal transplantation due to reversible, abnormal permeability of the blood-brain barrier Often manifests as headache followed by mental depression, visual loss, and seizures in the context of volume expansion, acute hypertension, and often treatment with corticosteroids or calcineurin inhibitors Lesions in the parietal, temporal, and occipital lobes may be seen on imaging studies.

Figure 82.3 Differential diagnosis of uremic encephalopathy.

raise the question of vasculitic neuropathy, especially when systemic vasculitis (e.g., ANCA-positive small-vessel vasculitis or polyarteritis nodosa) is causing the CKD. Functional sparing of small-diameter axons in uremia is suggested by relatively intact thermal thresholds (hot and cold thermal threshold testing is a surrogate for pain threshold). The modestly slowed nerve conduction velocities in the polyneuropathies of uremia may be related to the reversible inhibition of the sodium-potassium adenosine triphosphatase by a uremic toxin. According to the middle molecule hypothesis, accumulated toxins in the range of 300 to 12,000 d, including peptide hormones and polyamines, may lead to progression of neuropathy in HD patients.^{4,8,9} Lower limb motor axons in uremic patients are depolarized before but not after dialysis, consistent with a role of hyperkalemia in the development of altered nerve excitability.¹⁶ Elevated magnesium levels will also slow nerve conduction velocity. *In vitro*, extracellular acidosis contributes to decreased sodium conductance in large sensory neurons. Very slow nerve conduction velocities (i.e., less than half normal) suggest a demyelinating neuropathy, a finding that should lead the physician to seek a specific cause (e.g., a paraprotein).

Polyneuropathies occur in about two thirds of uremic patients and may progress rapidly in advanced CKD.^{1,16,17} Characteristic symptoms and signs are sensory loss, pain, paresthesias, and insensitivity to temperature, particularly cold. These findings can advance to include motor findings, such as footdrop. Phrenic neuropathy may cause dyspnea, whereas hiccups are more likely due to the central nervous system effects of uremia. The distal lower extremities are usually affected first because axonal polyneuropathies are length dependent. Decrease in vibratory sensation and position sense and Romberg sign (i.e., greater instability of stance with eyes closed than with eyes open) are common signs. Muscle stretch reflexes are reduced or absent. In the diabetic dialysis patient who has progressive neuropathy, it is important to establish adequacy of the dialysis as well as glucose control. Uremic polyneuropathy is aggravated by malnutrition, inadequately controlled hypertension, and a number of comorbid conditions, including diabetes mellitus, alcohol abuse, atherosclerotic vascular disease, and medications (e.g., nitrofurantoin, isoniazid, hydralazine).

The diagnosis of uremic polyneuropathy can usually be made on clinical findings. Nerve conduction velocity is modestly reduced, and needle electromyography shows evidence of chronic denervation and sometimes reinnervation. If electromyography and nerve conduction tests are performed, they should not be done in an extremity bearing an arteriovenous fistula as the surgery may cause local nerve injury, which can complicate the interpretation of the clinical neurophysiologic studies.¹⁶

Lead polyneuropathy should be considered, particularly when there is a known exposure history. Lead accumulates in the dialysis patient but could also be the cause of CKD. A lower motor neuron syndrome due to lead toxicity may be mistaken for amyotrophic lateral sclerosis. A bone lead scan using K-line x-ray fluorescence spectroscopy of the tibia is a promising new noninvasive test that may become useful. Serum lead values and red cell protoporphyrin levels may be normal if exposure is remote. There may be associated depression, the so-called saturnine temperament, so named because the ancients believed that Saturn was made of lead and was associated with a melancholy disposition. Gout, hypertension, renal glycosuria, and microcytic anemia also may be caused by lead toxicity.

Other conditions in the differential diagnosis of mixed polyneuropathy include other heavy metals (such as arsenic and mercury), nutritional deficiencies (such as pyridoxine, thiamine, and niacin), human immunodeficiency virus–related neuropathy, amyloid, vasculitis, sarcoid, lupus, and a paraneoplastic syndrome.

Progressive polyneuropathy may be an indication for initiation of dialysis or for renal transplantation. Symptoms usually will not deteriorate further or may even show a slow improvement thereafter. If polyneuropathic symptoms worsen in a dialysis patient, the dialysis dose should be increased. Physical therapy is an important component of the management. Patients experiencing neuropathic pain may be treated with tricyclic antidepressants (e.g., amitriptyline, 10 to 25 mg, increasing to 75 to 150 mg at bedtime) or antiepileptic drugs (e.g., carbamazepine, 200 to 400 mg initially, increasing to 1200 mg maximally; phenytoin, 100 to 200 mg initially, maximally 600 mg).^{1,2} Gabapentin is an antiepileptic drug that is sometimes used to treat neuropathy but is quite toxic in renal disease and is rarely necessary. When it is used, it should be monitored closely at reduced doses. Deficiencies of cobalamin (vitamin B₁₂), folate, and pyridoxine may be reflected in an elevated serum homocysteine level. Thiamine deficiency, often associated with malnutrition, can also aggravate

neuropathy, but whether replacement of any of these vitamins is effective in preventing or curing polyneuropathy in uremic patients is not well established. Thiamine deficiency is the cause of Wernicke's encephalopathy in dialysis or malnourished patients. This syndrome is suspected when the triad of mental change (often amnesia), ataxia, and oculomotor disturbances (most often abducens palsies with gaze-evoked nystagmus) is seen in any patient whose diet is deficient in B vitamins. When amnesia is combined with a polyneuropathy, the term *Korsakoff psychosis* applies. In malnourished patients, the cause of Korsakoff psychosis is usually multiple subclinical attacks of Wernicke's encephalopathy, hence the term *Wernicke-Korsakoff disease*.

Specific mononeuropathic syndromes include ulnar nerve entrapment, associated with uremic humoral calcinosis and subsequent ischemia, and carpal tunnel syndrome, for example, due to β_2 -microglobulin-derived amyloidosis (see Chapter 81) or to an arteriovenous fistula.^{1,17} These syndromes may be treated with anti-inflammatory agents, anticonvulsants, and surgical decompression. It is important to ensure adequacy of dialytic treatment.

AUTONOMIC NEUROPATHY

Autonomic neuropathy is also very common in patients with advanced CKD, probably because diabetes is a common cause of CKD. Hyperglycemia may be more difficult to control in CKD as glucose filtration is decreased. Amyloidosis, a less common cause of CKD, also is associated with autonomic neuropathy. A typical manifestation is orthostatic hypotension, which is most severe in patients with diabetes mellitus or amyloidosis as a cause of CKD. The low blood pressure may preclude antiproteinuric treatment with angiotensin antagonists in the predialysis patient and may complicate fluid removal during dialysis. CKD patients were thought to have decreased baroreceptor function, but normal baroreceptor responses to graded decrements in mean arterial blood pressure have been described.¹⁸ Instead, CKD patients have sympathetic hyperactivity, which contributes to hypertension, more rapid progression to renal failure in the predialysis patient, and greater cardiovascular risk. Accordingly, α - and β -adrenergic blockade has been advocated in CKD.¹⁸ Autonomic neuropathy is due to axonal disease and thus is length dependent. For that reason, the longest autonomic nerve, the vagus, is usually the first affected, resulting in the loss of the normal sinus arrhythmia, significant reductions of day-night blood pressure variation, and possibly sudden cardiac death related to the loss of the balance between the sympathetic and parasympathetic limbs of the autonomic nervous system. Gastrointestinal complaints include gastroparesis, particularly problematic for the diabetic patient. In the predialysis patient, nausea and early satiety associated with gastroparesis may be confused with uremia. Nocturnal diarrhea is another consequence of vagal neuropathy. Erectile dysfunction and incontinence (urinary more common than fecal) may also be related to autonomic neuropathy.

CRANIAL NEUROPATHIES

Cranial nerve involvement is most often vestibulocochlear. Hearing loss needs to be distinguished from drug-induced ototoxicity or the neurosensory deafness of hereditary nephropathy.^{1,2} Bilateral vestibular failure leads to inability to stand or to walk normally without vertigo or nystagmus. It is often related to the use of aminoglycoside antibiotics in the patient with CKD,

unless the dose is properly adjusted. *N*-Acetylcysteine given with aminoglycosides may reduce the risk of cochlear toxicity. Sulfa-based loop diuretics often used at high dose in CKD may cause vestibular or cochlear damage. Decreased olfactory function, especially a reduced ability to discriminate among and to identify odors, and dysgeusia are commonly seen in patients with CKD.

SLEEP DISORDERS

Many HD and peritoneal dialysis patients exhibit obstructive sleep apnea that is independent of obesity.¹⁹ The associated sleep deprivation contributes to fatigue and cognitive impairment and increases the risk of cardiovascular complications.¹⁹ Both obstructive and central sleep apnea are seen in patients with CKD. Treatment of obstructive sleep apnea, with use of continuous positive airway pressure in a fashion similar to the treatment of nonuremic individuals, is effective. Nocturnal HD significantly reduced the occurrence of sleep apnea.¹⁹

Daytime sleepiness is common and underdiagnosed in patients with CKD and contributes not only to worsened hypertension and increased cardiovascular risk but also to social dysfunction. Whether obstructive sleep apnea and its associated excessive daytime sleepiness is an independent risk factor for the progression of renal failure is not yet settled. It is assessed by a multiple sleep latency test, that is, the duration of time from "lights out" to the onset of sleep. If it is less than 5 minutes, it is consistent with sleep deprivation. There was also a reduced proportion of rapid eye movement sleep. An increased arousal frequency is related to periodic limb movements during sleep and the presence of sleep apnea.

Sleep-wake complaints are common in patients on dialysis, with an incidence of up to 80%. Contributors include peripheral neuropathy, pain, and pruritus.

RESTLESS LEGS SYNDROME (THE EKBOM SYNDROME)

Restless legs syndrome (RLS), described by K. A. Ekbom in 1944,²⁰ is frequent in CKD, particularly in women. It may result from a decrease in dopaminergic modulation of intracortical excitability, with reduced supraspinal inhibition and increased spinal cord excitability. RLS is characterized by unpleasant "creeping" sensations in the extremities and a compulsive need to move the limbs, usually the legs.²¹⁻²³ The movement is worsened by periods of rest or inactivity and is relieved by walking or stretching. Symptoms are worse at night and may lead to insomnia and consequent daytime sleepiness and reduced quality of life. Nocturnal muscle cramps are also common in CKD and should be distinguished from the RLS. The Ekbom syndrome consists of restless legs plus other obsessive-compulsive-like disorders including various pica behaviors, such as pagophagia (ice eating), geophagia (clay eating), and amylophagia (starch eating).

Periodic limb movements is a disorder characterized by episodes of involuntary repetitive extension of the big toe and dorsiflexion of the ankle as well as flexion of the knee and hip.^{22,23} This disorder is more likely to occur in those with RLS.

Iron deficiency or iron transport into the central nervous system plays a central role in RLS. Iron is a cofactor for the enzyme tyrosine hydroxylase, the rate-limiting step in the biosynthesis of dopamine, possibly explaining the link between iron deficiency and dopamine deficiency in RLS. Overt iron deficiency is easily diagnosed and should be treated.^{22,23} In patients

with normal red blood cell indices and serum iron and total iron-binding capacity, serum ferritin should be tested. Transferrin saturation ratio may be an even more sensitive indicator of iron deficiency. If these are both normal, a spinal fluid ferritin analysis may reveal a subtle central nervous system iron deficiency syndrome. RLS often persists after initiation of dialysis but may improve after transplantation and has been linked to abnormalities in calcium and phosphorus metabolism as well as to anemia. Iron replacement should be initiated if there is any indication of iron deficiency. Oral replacement is the safest method. Although intravenous iron may be effective, this has not been demonstrated in carefully controlled clinical trials in this setting. Dopaminergic treatment is often helpful, usually starting with the dopamine receptor agonists pramipexole and ropinirole. Levodopa combined with decarboxylase inhibitors (e.g., Sinemet) may be used as well as gabapentin, opioids, and benzodiazepines.²¹⁻²³ Care should be taken with gabapentin because of toxicity with accumulation, the symptoms of which are sedation, cognitive slowing, and various movement disorders including tremor and asterixis (see previous discussion). Older dopamine receptor agonists, such as bromocriptine and pergolide, are rarely used now for RLS.

NEUROLOGIC SYNDROMES ASSOCIATED WITH RENAL REPLACEMENT THERAPY

Renal replacement therapy is associated with an increased incidence of subdural hematoma and intracranial hemorrhage, presumably connected to hypertension and anticoagulation with HD as well as Wernicke's encephalopathy (see earlier discussion).^{1,2} A syndrome of muscle weakness has been attributed to L-carnitine depletion from dialysis, leading to decreased mitochondrial fatty acid utilization.

Dialysis disequilibrium syndrome is a rare complication of rapid metabolic changes occurring with HD, usually affecting patients in whom HD is being initiated (see also Chapter 91).²⁴ It is most common in those patients with severe uremia of long duration and with severe hypertension. Characterized by acute onset of headache, nausea, vomiting, disorientation, a confusional state, and seizures, it is a diagnosis of exclusion. It usually results from acute changes in osmolality during HD, in which the rapid decrease in urea in the extracellular fluid favors water movement into brain cells, resulting in cerebral edema. Alternatively, other intracellular osmolytes within brain cells may draw water from the extracellular fluid. The syndrome normally reverses spontaneously after a period of regular HD. If no improvement is seen after a month of HD, one should investigate for other possible causes of the clinical syndrome by imaging the brain, obtaining an electroencephalogram, and examining the spinal fluid. Dialysis disequilibrium syndrome may be prevented by decreasing HD length to 2 to 3 hours, dialyzing daily, and reducing HD efficacy during the first sessions.

Dialysis encephalopathy (formerly called dialysis dementia) is probably a multifactorial syndrome occurring in sporadic-endemic and epidemic types. In particular, in the epidemic type, aluminum-based phosphate binders and exposure to a dialysate containing more than 20 µg/l aluminum are considered to be major causes.^{25,26} Aluminum transferred to the nervous system by transferrin results in a characteristic clinical condition with prominent stuttering that usually worsens toward the end of a dialysis session and encephalopathy, initially responding well to

intravenous benzodiazepines but then becoming unresponsive, leading to a severe encephalopathy and death. With the almost universal preparation of dialysate water by reverse osmosis and the marked reduction in aluminum-containing phosphate binder use, aluminum-induced encephalopathy has virtually disappeared. If it is present, aluminum toxicity is treated with deferoxamine (see Chapter 81). Renal transplantation is an effective treatment of dialysis dementia.

Gastroenterology and Nutrition in Chronic Kidney Disease

Gemma Bircher, Graham Woodrow

GASTROINTESTINAL PROBLEMS IN CHRONIC KIDNEY DISEASE

Gastrointestinal (GI) symptoms and disease are common in patients with chronic kidney disease (CKD), including those receiving renal replacement therapy (Fig. 83.1). Anorexia, nausea, and vomiting can arise from uremic toxicity. These may indicate the need to start dialysis or may be a manifestation of inadequate dialysis clearances. GI disturbances contribute to the development of malnutrition and wasting. These common complications of advanced CKD carry an adverse prognosis for survival. Some GI conditions are a result of uremia or the effects of renal replacement therapy. Other GI symptoms are manifestations of conditions also responsible for the renal disease. Medications used in patients with CKD may result in a range of GI complications.

GASTROINTESTINAL DISEASE IN CHRONIC KIDNEY DISEASE

Oral Disease in Chronic Kidney Disease

Glossitis can result from iron, vitamin B₁₂, or folic acid deficiency anemia. Halitosis is a feature of uremia, and reduced taste sensation or abnormal or unpleasant taste can impair dietary intake. Dental disease may prevent adequate nutrition. Gingival hyperplasia is a frequent complication of treatment with calcium channel blockers or cyclosporine. Oral candidiasis occurs in patients receiving immunosuppressive drugs including corticosteroids, with antibiotic therapy, in patients with diabetes, and in older malnourished individuals. If extensive, particularly with esophageal involvement, it may lead to dysphagia (Fig. 83.2).

Gastroesophageal Reflux Disease and Esophagitis

This common complaint is defined by symptoms of heartburn or mucosal changes arising from reflux of caustic gastric contents into the esophagus. It occurs more frequently in CKD because of GI dysmotility or delayed gastric emptying and may be more prevalent in peritoneal dialysis (PD) because of increased intra-abdominal pressure.¹ It is more common in patients with scleroderma because of reduced esophageal peristalsis. Esophagitis also results from the irritant effects of drugs, including slow-release potassium preparations, tetracyclines, iron preparations, aspirin, nonsteroidal anti-inflammatory drugs, and bisphosphonates.

The diagnosis is made from the patient's symptoms. Typical features occur on endoscopy but may be absent in symptomatic patients. Other investigations include 24-hour ambulatory esophageal pH monitoring and demonstration of reflux on barium swallow examination. It is important to consider ischemic cardiac disease in CKD as an alternative cause of atypical symptoms. Management includes weight loss if the patient is obese; avoidance of bedtime snacks, fatty foods, cigarettes, and alcohol; and raising the head of the patient's bed. Proton pump inhibitors are the most effective medical treatment, and maintenance therapy may be required. Other drugs include H₂ receptor antagonists and antacid preparations. Sucralfate should be avoided in CKD because of the risk of aluminum accumulation.

Peptic Ulcer Disease, Gastritis, and Duodenitis

In the early days of dialysis, peptic ulceration and GI hemorrhage were major complications of renal failure. However, with effective drug therapies and improvement in dialysis therapy, peptic ulcer disease is not more common in CKD than in the general population, although it remains an important cause of GI hemorrhage. Peptic ulcers in CKD are more often multiple than in the general population and situated in a post-bulbar position.² Hemorrhage occurs more often, but pain is less frequent.²

Gastritis and duodenitis are common in patients with CKD and abdominal symptoms. Hypergastrinemia occurs in CKD but is not important in causation of gastritis, duodenitis, or peptic ulcers. Despite high urea concentrations in patients with CKD, *Helicobacter pylori* infection is not increased. Increased susceptibility of gastric and duodenal mucosa to damage in CKD may be an underlying mechanism. The presence of *H. pylori* infection in PD has been suggested as a possible cause of anorexia, inflammation, and malnutrition.³

Dyspepsia without other warning features (weight loss, vomiting, hemorrhage) may be managed by testing for *H. pylori* with a breath test or stool antigen test (which are valid in CKD) and an empirical course of acid-suppressing therapy. Persistent symptoms of new onset in patients older than 55 years warrant upper GI endoscopy to exclude malignant disease. The frequent coexistence of other symptoms in CKD, such as nausea, vomiting, and weight loss, may lead to a lower threshold for performing endoscopy. Management includes use of proton pump inhibitors and H₂ receptor antagonists. There is a risk of excess calcium and magnesium absorption with some antacids in CKD, and aluminum- or bismuth-containing preparations should be avoided.

Important Causes of Common GI Symptoms in Patients with CKD	
Clinical Feature	Important Causes in CKD
Anorexia	Uremic toxicity Inadequate dialysis clearances Delayed gastric emptying
Nausea and vomiting	Uremic toxicity Delayed gastric emptying Gastritis/duodenitis Peptic ulcer disease
Constipation	Drugs – including opioid analgesia GI pseudo-obstruction Diverticular disease
Diarrhea	Diabetic enteropathy Dialysis-related amyloidosis Diverticular disease Clostridium difficile infection
GI hemorrhage	Gastritis/duodenitis Esophagitis Peptic ulcer disease Angiodysplasia Intestinal ischemia Dialysis-related amyloidosis Vasculitis
Acute abdominal pain	Gastritis/duodenitis Complications of peptic ulcer disease Acute pancreatitis Intestinal ischemia Diverticulitis GI pseudo-obstruction Colonic perforation due to fecal impaction Complications of peritoneal dialysis (peritonitis, dialysis catheter malposition, dialysate infusion pain) Complications of autosomal dominant polycystic kidney disease Retroperitoneal hemorrhage

Figure 83.1 Important causes of common GI symptoms in patients with CKD.

Delayed Gastric Emptying and Gastroparesis

Gastric emptying is impaired in uremia (possibly to a greater degree in PD)^{4,5} and is affected by some conditions leading to renal disease, particularly diabetes and amyloidosis. This results in reduced appetite, early satiety, nausea, vomiting, and malnutrition. Mechanisms in uremia may include autonomic neuropathy and retained GI peptides. The diagnosis is confirmed by scintigraphic measurement of gastric emptying. It may be suspected when endoscopy demonstrates residual gastric contents despite fasting. Endoscopy is important to exclude gastric outlet obstruction. Reversible causes should be addressed, including optimization of diabetic control, correction of electrolyte abnormalities, and discontinuation of drugs that impair gastric emptying (e.g., those with anticholinergic and opioid effects). Dietary measures, with frequent smaller low-fat meals and avoidance of

Figure 83.2 Endoscopic appearance of esophageal candidiasis. (Courtesy Dr. B. Rembacken, Leeds, UK.)

nondigestible solids, are often disappointing. Antiemetic agents are also often ineffective. The mainstay of treatment is prokinetic drug therapy, including metoclopramide, domperidone, and erythromycin. Prokinetic drugs improve nutritional state in patients with delayed gastric emptying.⁶ Nutritional support through feeding nasogastric or jejunostomy tubes may be required.

Large Bowel Disorders

Diverticular disease has an incidence in CKD similar to that in the general population, except in patients with autosomal dominant polycystic kidney disease (ADPKD), in whom it is increased.⁷ It presents as acute diverticulitis or colonic perforation and is associated with PD peritonitis due to enteric organisms. There is a greater risk of bleeding in CKD (due to uremic bleeding tendency) and perforation with high-dose corticosteroids (e.g., after renal transplantation).

Constipation is common in CKD. Predisposing factors include drugs, dietary restrictions, low oral fluid intake, and electrolyte abnormalities, including hypercalcemia. In PD, constipation results in impaired dialysate drainage and catheter malposition. Severe constipation is a risk factor for large bowel perforation. Management includes stool-softening agents, stimulant laxatives, and fiber preparations. Drugs predisposing to constipation include calcium-based phosphate binders, sevelamer, oral iron, opioid analgesics, and calcium resonium.

Colonic perforation may occur in CKD from a number of causes. These include diverticulitis, fecal impaction, and dialysis-related amyloidosis. This condition has a higher mortality in CKD patients.

Gastrointestinal Pseudo-obstruction

Pseudo-obstruction presents with acute or more chronic clinical features of abdominal pain, vomiting, constipation, or diarrhea. It arises from disordered gut motility and is more common in dysmotility states, such as diabetes, amyloidosis, and scleroderma. Drugs reducing bowel motility and electrolyte disturbance such as hypokalemia predispose to pseudo-obstruction, and it may be acutely precipitated by surgery, constipation, and retroperitoneal hemorrhage. Investigations include plain abdominal radiography, computed tomographic scanning, and bowel

Figure 83.3 Two examples of gastric angiodysplasia in a dialysis patient. (Courtesy Drs. R. Winograd and C. Trautwein, Aachen, Germany.)

contrast studies. Management includes nutritional support (which may require parenteral feeding) and prokinetic agents. Nasogastric tube insertion and aspiration may be required for symptomatic control. Complications include intestinal perforation⁸ and bacterial overgrowth.

Vascular Disease of the Gastrointestinal Tract

Intestinal ischemia is an important cause of an acute abdomen in older CKD patients. A proportion of cases result from nonocclusive mesenteric ischemia, in which there is no critical vascular occlusion.⁹ It may be precipitated by excess fluid removal by hemodialysis (HD). Predisposing factors include hypotension, cardiac failure, hypoxia, increased plasma viscosity, and constipation (which increases intraluminal pressure, impairing vascular perfusion). Presentation is with abdominal pain, diarrhea, or lower GI bleeding. Abdominal signs such as peritonism can be misleadingly modest at presentation, but there is often peripheral neutrophil leukocytosis and progressive lactic acidosis. Milder cases may settle with hemodynamic resuscitation. More severe cases with features of peritonism and intestinal infarction require laparotomy and have a high mortality.

Gastrointestinal Hemorrhage

GI hemorrhage is an important complication of CKD, with increased incidence compared with the general population. Causes include a greater incidence of lesions such as gastritis and duodenitis,¹⁰ angiodysplasia (Fig. 83.3), and, more rarely, dialysis-related amyloidosis and systemic vasculitis. Uremic hemostatic defects and anticoagulation during HD are also important. Upper GI endoscopy is the major diagnostic investigation in upper GI bleeding and also allows therapeutic procedures to stop bleeding. Flexible sigmoidoscopy and colonoscopy are performed in lower GI bleeding. Investigations where the cause remains unclear include angiography, small bowel enteroscopy or capsule study, and radiolabeled red cell scanning.

Resuscitation requires careful monitoring in CKD. Adequate fluid replacement to maintain renal perfusion in subjects not on dialysis or residual renal function in patients on dialysis, but avoiding fluid overload, is crucial. Monitoring of serum potassium with avoidance of hyperkalemia complicating blood transfusion is also important. Correction of coagulation defects in

Figure 83.4 Computed tomographic appearance of *Clostridium difficile* colitis in a hemodialysis patient, demonstrating pancolitis with markedly edematous haustra (arrows) after treatment with broad-spectrum antibiotics. (Courtesy Dr. M. Weston, Leeds, UK.)

CKD includes optimization of dialysis clearance, correction of anemia, and use of DDAVP or cryoprecipitate. Drugs increasing bleeding risk should be discontinued when possible. HD, when it is required, should be performed without heparin for anticoagulation. Specific treatment is directed against the cause of hemorrhage. Bleeding from angiodysplasia in HD may improve on transfer to PD.¹¹ The presence of CKD increases the risk of mortality in GI hemorrhage.¹⁰

Clostridium difficile Infection

Clostridium difficile is a major cause of nosocomial diarrheal illness. Clinical manifestations vary from mild diarrheal illness to severe pseudomembranous colitis (Fig. 83.4). Patients with CKD are at risk of more frequent or severe infection and have

a higher resulting mortality.¹² Reasons include the older age of CKD patients, frequent use of acid-suppressing drugs, and antibiotics. Diagnosis is made by identifying *C. difficile* toxin in diarrheal stools. In severe cases, there are radiologic appearances of acute colitis with mucosal edema, but these are not specific for *C. difficile*. A pseudomembrane may be visualized on sigmoidoscopy, but diarrhea can occur in its absence. The precipitating antibiotic should be stopped if possible. Oral metronidazole is first-line therapy; oral vancomycin is used if there is intolerance of or failure to respond to metronidazole. Drugs to reduce diarrhea or impairing gut motility must be avoided as they may precipitate toxic megacolon. Colectomy may be required in life-threatening disease. *C. difficile* infection is a major problem in the hospital setting, including renal units. Preventive measures, including hand washing, cleanliness of physical environment, and isolation of affected inpatients with barrier nursing, are essential. Antibiotic policies should minimize use of broad-spectrum antibiotics, which induce *C. difficile* infection.

Acute Pancreatitis

There is some evidence suggesting that acute pancreatitis is more common in CKD, and incidence may be greater in PD than in other CKD patients.¹³ Most cases are secondary to biliary tract disease or alcohol or are idiopathic. Rarer causes, in CKD patients, are hypercalcemia, vasculitis, and drugs including corticosteroids, azathioprine, angiotensin-converting enzyme (ACE) inhibitors, and diuretics. Serum amylase is the usual diagnostic measure, although concentrations are normally elevated up to threefold in renal failure and are lowered in PD patients receiving icodextrin dialysate. Serum lipase is an alternative diagnostic marker (although it is also elevated in uremia). Amylase and lipase concentrations may be measured in dialysate in PD patients with suspected pancreatitis. Radiology, including ultrasound, computed tomography, and magnetic resonance imaging, is useful to confirm the diagnosis and to detect underlying biliary disease and complications such as pancreatic necrosis and pseudocyst formation. In PD patients with acute pancreatitis, dialy-

sate may become cloudy with increased leukocytes, hemorrhagic, or dark brown (cola colored).

Acute Abdomen

Some causes of acute abdominal pain occur more commonly in or are specific to CKD patients. A high index of suspicion for ischemic bowel is important because of the frequency of vascular disease in CKD. Pain may result from complications of autosomal polycystic kidney disease. Retroperitoneal hemorrhage can arise from anticoagulation, including during HD. In PD, abdominal pain arises from peritonitis, dialysate infusion pain due to acidity of the fluid, catheter malposition, constipation, and encapsulating peritoneal sclerosis. Other surgical conditions need to be distinguished from dialysis-specific causes. Although air uncommonly enters the peritoneal cavity during PD, in the setting of acute abdominal symptoms, the finding of free gas on radiologic imaging of the abdomen suggests visceral perforation.

GASTROINTESTINAL-RENAL SYNDROMES

A number of conditions result in both renal and GI manifestations (Fig. 83.5).

Diabetes

Diabetes is commonly complicated by disordered gut motility. Gastroparesis needs to be distinguished from uremic upper GI symptoms. Diarrhea due to diabetic enteropathy is also common, classically is nocturnal, and usually is neurogenic in origin. Bacterial overgrowth is uncommon and is diagnosed by the hydrogen breath test. GI symptoms may be exacerbated by drug treatments for diabetes, including metformin and α -glucosidase inhibitors. Gastroparesis results in difficulties with glycemic control, fluid and electrolyte imbalance, drug malabsorption, and malnutrition. Colonic transport time is increased in diabetes, resulting in constipation.

Gastrointestinal-Renal Syndromes: Conditions Typically Resulting in Both Renal and GI Disease		
Disorder	Renal involvement	GI involvement
Diabetes	Proteinuria, CKD	Gastroparesis, diabetic enteropathy, constipation
Systemic vasculitis	Proliferative glomerulonephritis, CKD	Intestinal ischemia, GI hemorrhage, bowel perforation, hepatobiliary involvement, acute pancreatitis
Systemic amyloidosis	Nephrotic syndrome, CKD	Diarrhea, malabsorption, splenic rupture
Autosomal dominant polycystic kidney disease	CKD, cyst hemorrhage and infection	Abdominal pain (from renal or hepatic cysts), diverticular disease, hernia
Inflammatory bowel disease	AA amyloidosis, drug-induced interstitial nephritis, IgA nephropathy, oxalate renal calculi (with terminal ileal Crohn's disease)	Abdominal pain, diarrhea, GI hemorrhage, malabsorption
Scleroderma	CKD, acute scleroderma renal crisis	Dysphagia, constipation, malabsorption and bacterial overgrowth
Fabry's disease	Hematuria, proteinuria, CKD	Abdominal pain, episodes of diarrhea or constipation
Coeliac disease	IgA nephropathy	Malabsorption, iron-deficiency anemia

Figure 83.5 Gastrointestinal-renal syndromes: conditions typically resulting in both renal and GI disease.

Figure 83.6 GI side effects of drugs commonly used in patients with CKD. ACE inhibitors, angiotensin-converting enzyme inhibitors.

GI Side Effects of Drugs Commonly Used in Patients with CKD	
Drug	GI Side Effects
Calcium-based phosphate binders	Constipation, abdominal discomfort
Sevelamer	Constipation, dyspepsia, bowel obstruction (very rare)
Lanthanum carbonate	Dyspepsia, nausea, diarrhea
Cinacalcet	Anorexia, nausea, vomiting
Statins	Abdominal discomfort, diarrhea, constipation
ACE inhibitors	Nausea, constipation, diarrhea, acute pancreatitis
Iron supplements	Nausea, epigastric pain, constipation, diarrhea
Bisphosphonates	Esophagitis, esophageal ulcers and strictures
Polystyrene sulphonate (calcium resonium/kayexalate)	Severe constipation, colonic necrosis
Calcium channel blockers	Constipation, intestinal pseudo-obstruction
Metformin	Anorexia, nausea, vomiting, diarrhea
Proton pump inhibitors	Nausea, vomiting, abdominal pain, constipation, diarrhea
Mycophenolate mofetil	Diarrhea, abdominal pain, vomiting
Azathioprine	Dyspepsia, acute pancreatitis, hepatitis

Systemic Vasculitis

GI manifestations of vasculitis include intestinal ischemia or infarction, hemorrhage, and perforation with peritonitis. Abnormal liver function test results arise from hepatitis, and cholecystitis and pancreatitis have been described. Serositis with abdominal pain is a feature of systemic lupus erythematosus. Abdominal pain, vomiting, and GI hemorrhage are typical of Henoch-Schönlein purpura.

Systemic Amyloidosis

Primary AL amyloidosis may result in both renal and GI involvement. Conversely, inflammatory bowel disease is an important cause of secondary AA amyloidosis, which may result in renal involvement. Thus, in a patient with renal amyloidosis who has GI symptoms, it is important to characterize the type of amyloid and the underlying cause of GI disturbance.

Autosomal Dominant Polycystic Kidney Disease

Abdominal hernias are more common in ADPKD¹⁴ and are a particular problem in PD patients. Colonic diverticular disease occurs more frequently. The enlarged kidneys can result in abdominal pain, hemorrhage, abdominal fullness, and anorexia. Hepatic cysts and occasionally massive hepatomegaly may cause chronic abdominal pain and fullness. Common bile duct dilation, of uncertain significance, occurs more frequently in ADPKD.

Inflammatory Bowel Disease

Inflammatory bowel disease may be complicated by AA amyloidosis and IgA nephropathy. Drug therapy, such as aminosalicylates, can lead to renal disease, including chronic interstitial nephritis. Terminal ileal disease in Crohn's disease can lead to hyperoxaluria and oxalate calculi.

Celiac Disease

Celiac disease is a relatively common condition and occurs with increased frequency in association with other autoimmune conditions, such as diabetes mellitus. There is also a reported association with IgA nephropathy.¹⁵

DRUGS AND GASTROINTESTINAL DISEASE IN CHRONIC KIDNEY DISEASE

Drugs commonly used in CKD can lead to GI problems (Fig. 83.6). Phosphate-binding drugs commonly result in abdominal symptoms. Nausea and vomiting are important complications of cinacalcet. Other drugs important in CKD that may cause GI problems include statins, ACE inhibitors, iron supplements, sodium bicarbonate, bisphosphonates, and metformin. Acid-suppressing drugs including proton pump inhibitors and H₂ receptor blockers are commonly prescribed in CKD. They are often inappropriately continued for long periods¹⁶ and have their own associated side effects. They increase the risk of *C. difficile* infection. Proton pump inhibitors can result in symptoms including nausea, vomiting, abdominal pain, diarrhea, and constipation.

SPECIFIC GASTROINTESTINAL COMPLICATIONS OF RENAL REPLACEMENT THERAPY

Idiopathic Dialysis-Related Ascites

Idiopathic ascites occurs in HD patients and may be due to suboptimal dialysis clearances. Diagnosis is by exclusion of other causes of ascites. Aspirated fluid usually has an elevated protein content. Management includes fluid and sodium intake restriction and ultrafiltration by dialysis. Small solute clearance must be optimized, and paracentesis may be required for symptom

Figure 83.7 Hemoperitoneum: blood-stained peritoneal dialysate in a peritoneal dialysis patient who has developed acute pancreatitis.

control. It may resolve after renal transplantation, and switching to PD can be tried.

Peritoneal Dialysis–Related Gastrointestinal Conditions

A number of complications relating to PD may affect the abdomen, including infectious peritonitis, pain on dialysate infusion and drainage, and encapsulating peritoneal sclerosis (see Chapter 93). Hemoperitoneum in PD is typically related to the menstrual cycle, occurring during menstruation or ovulation, or may be self-limited, probably resulting from minor peritoneal membrane trauma from the PD catheter (Fig. 83.7). Rarely, underlying pathologic causes are present, including encapsulating peritoneal sclerosis, malignant disease, pancreatitis, hepatobiliary disease, and hemorrhage from polycystic kidneys.

Dialysis-Related Amyloidosis

Amyloidosis due to deposition of β_2 -microglobulin in very rare patients on long-term dialysis can result in GI manifestations. These include GI hemorrhage, diarrhea, pseudo-obstruction, ischemia, and perforation (see Chapter 81).

Transplantation and Gastrointestinal Disturbance

A variety of GI problems occur after renal transplantation (see Chapters 100 and 101). Gastritis or duodenitis results from corticosteroid therapy, and mycophenolate mofetil commonly leads to diarrhea, abdominal pain, or vomiting. Infectious complications of the GI tract include oral and esophageal candidiasis, cytomegalovirus disease, and diarrhea from *C. difficile*. Post-transplantation lymphoproliferative disease may also involve the GI tract.

NUTRITION IN CHRONIC RENAL FAILURE

Nutrition plays an important role in the management of hypertension, obesity, hyperlipidemia, and diabetes, all of which affect CKD progress. As the glomerular filtration rate (GFR) deteriorates, retention of nitrogenous metabolites, decreased ability to regulate levels of electrolytes and water, and certain vitamin

deficiencies can be affected by dietary changes. In addition, protein-energy depletion predicts a poor outcome.

Malnutrition: Protein-Energy Wasting

In kidney disease, there are often conditions that lead to wasting that are not related to reduced intake alone. Many terms exist to indicate malnutrition in CKD, including uremic malnutrition, protein-energy malnutrition, and malnutrition–inflammation complex syndrome. In 2008, the International Society of Renal Nutrition and Metabolism recommended that the term *protein-energy wasting* be used for loss of body protein and fuel reserves.¹⁷

The prevalence of protein-energy wasting in dialysis patients ranges from 10% to 70%, depending on the choice of nutritional marker and the population studied.^{18,19} There is also diminished nutritional status before initiation of dialysis, which strongly predicts mortality on dialysis. Paradoxically, several investigators have found a significant inverse relationship between mortality risk and body size in HD populations, a phenomenon termed reverse epidemiology (see Chapter 78).

Several factors related to the uremic state may contribute to the high incidence of protein-energy wasting:

- Inadequate protein and calorie intake: nutrient intake parallels the decrease of GFR and is largely driven by CKD-associated anorexia.²⁰ This anorexia is due to impaired taste acuity and diminished olfactory function, medications, autonomic gastroparesis, psychological and socioeconomic factors, and inadequate dialysis. Elevated serum leptin, a long-term regulator of appetite, has also been linked to the anorexia seen in CKD.²¹
- Nutritional losses occur during treatment: 8 to 12 g of amino acids is lost per HD treatment, and 5 to 10 g of protein is lost daily during PD, depending on the peritoneal membrane transport type. This may be significantly higher during episodes of PD peritonitis.
- Metabolic acidosis, periods of acute or chronic illnesses, and the use of bioincompatible dialysis membranes, such as cuprophane, may induce protein catabolism. This is mediated in large part through the ubiquitin-proteasome pathway of protein degradation.²²
- Protein catabolic effects that can further compromise patients early after transplantation include large doses of corticosteroids, the stress response to surgery, and delayed graft function.
- Inflammatory state of uremia (see also Chapter 78).²³
- Endocrine disorders, such as insulin resistance, increased parathyroid hormone concentrations (which may promote amino acid catabolism and gluconeogenesis), and vitamin D deficiency (which can contribute to proximal myopathy), may have an adverse effect on nutritional status.

Assessment of Nutritional Status

The measurement of nutritional status does not lend itself to one simple test, and a panel of measures is required for optimal screening of nutritional status. Figure 83.8 summarizes some of the methods used for assessment of nutritional status.

Estimation of Intake

Diet history, recall, and food diaries are the mainstays for estimation of dietary intake. In addition, a gradual decrease in blood urea nitrogen and reduced phosphate and potassium levels may indicate a decrease in protein intake in dialysis-dependent

Figure 83.8 Assessment of nutritional status. Methods used to assess nutritional status are shown. PNA, protein equivalent of total nitrogen appearance; PCR, protein catabolic rate (mathematically identical to PNA). The creatinine index is measured as the sum of creatinine removed from the body (measured from the creatinine removed in dialysate, ultrafiltrate and/or urine), any increase in the body creatinine pool, and the creatinine degradation rate. See also <http://www.kidney.org/professionals/kdoqi>

Assessment of Nutritional Status	
Area	Assessments
Physical examination	
Assessment of dietary intake	Diet history, food diaries, appetite assessment questionnaires
Anthropometric measurements	Body weight, height, body mass index Percentage weight change Skinfold thickness Midarm muscle circumference
Body composition	Neutron activation Near-infrared resistance Bioelectrical impedance Dual-energy x-ray absorptiometry (DEXA) Total body potassium
Biochemical determinations	Serum electrolytes Serum proteins PNA, PCR Serum cholesterol Creatinine index
Nutritional scoring systems	Subjective global assessment
Immunologic assays	Blood lymphocytes Delayed cutaneous hypersensitivity tests
Functional tests	Grip strength

patients, and low serum cholesterol level may indicate a poor calorie intake.

The excretion of the protein end-product urea is easily measured and is often used to estimate adequacy of dialysis. The protein equivalent of total nitrogen appearance (PNA) can be estimated on HD from interdialytic changes in urea nitrogen concentration in serum and the urea nitrogen content of urine and dialysate. nPNA is the term for PNA related to body weight. On the basis of the assumption that nitrogen excretion equals nitrogen intake in steady state, nPNA has been used to approximate dietary protein intake in the short term. Results, however, need to be interpreted with caution (urea kinetic modeling and adequacy of dialysis are further discussed in Chapters 89 and 90). Equations for estimation of nPNA have been recommended by the Kidney Disease Outcomes Quality Initiative (KDOQI).²⁴

Body Composition

A range of techniques are available that can distinguish body compartments on the basis of physical characteristics, which can provide information about nutritional state (body lean tissue and fat content) and hydration.

Skinfold thickness can be used to assess body fat, and muscle mass can be assessed by measurement of mid-upper arm muscle circumference (MAMC; Fig. 83.9). The midpoint of the upper dominant arm is used, as this is the arm less likely to have an arteriovenous fistula.

$$\text{MAMC (cm)} = \text{midarm circumference (cm)} - [3.14 \times \text{triceps skinfold (cm)}]$$

The measurement is taken after dialysis for patients on HD. Although they are inexpensive and relatively easy to learn and quick to carry out, these anthropometric measurements are limited by intervariability and intravariability. Nevertheless,

Figure 83.9 Routine measurement of skinfold thickness. The dominant arm that does not have an arteriovenous fistula or graft is used in patients with renal failure.

serial measures over time can be useful to track changes in the same patient when they are used in conjunction with other nutritional indices.

Subjective global assessment (SGA) is a reliable nutritional assessment tool for patients on dialysis.²⁵ A series of questions

Figure 83.10 A severely malnourished hemodialysis patient. There is marked wasting of the quadriceps and calf muscles.

Figure 83.11 A severely malnourished hemodialysis patient. Muscle wasting around clavicle and shoulder.

about recent changes in nutrient intake are used with simple observations of the patient's body weight and muscle mass to determine subjectively the nutritional status of the individual; patients are classified as well nourished, mildly malnourished/suspected malnutrition, or severely malnourished. Figures 83.10 and 83.11 show muscle wasting in a patient on HD classified by SGA as severely malnourished. SGA is by definition subjective and has been criticized for being insufficiently sensitive to define the degree of malnutrition. Other scoring systems using components of the conventional SGA are presently being evaluated.

Visceral Protein

Fluid status, impaired liver function, age, and acute inflammatory conditions can all affect albumin levels. However, despite its relatively long half-life (20 days), albumin still remains an important measure of nutritional status and health of the patient.

Figure 83.12 White nails in hypoalbuminemia. The white band grew during a transient period of hypoalbuminemia caused by nephrotic syndrome.

Some Indices of Malnutrition

Assessment	Indices
Biochemical parameters	<p>Serum albumin below the normal range</p> <p>Serum prealbumin <300 mg/l (30 mg/dl) (for maintenance dialysis patients only as levels may vary according to GFR level for CKD 2-5)</p> <p>Low serum creatinine, phosphate, potassium, urea in patients on dialysis</p> <p>Serum cholesterol <150 mg/dl (3.8 mmol/l)</p> <p>Low creatinine index</p> <p>Low PNA, PCR</p>
Anthropometric parameters	<p>Continuous decline in weight, skinfold thickness, midarm muscle circumference</p> <p>Body mass index <20</p> <p>Body weight <90% of ideal</p> <p>Abnormal muscle strength</p>

Figure 83.13 Some indices of malnutrition. GFR, glomerular filtration rate; PNA, protein equivalent of total nitrogen appearance; PCR, protein catabolic rate.

Clinically, it may be possible to observe the growth of white nails when there has been a transient period of hypoalbuminemia (Fig. 83.12). Other serum protein markers of nutritional status are also difficult to interpret because of the influence of factors other than nutrition. Serum transferrin is linked to body iron stores and may be altered with changes in iron status. Prealbumin levels can be increased by CKD because of impaired metabolism in the kidney. Levels of prealbumin also decline rapidly during episodes of acute inflammation.

With the low specificity and sensitivity of many of the anthropometric and biochemical markers, it becomes clear that integration of a range of measurements along with evaluation of the subjective well-being of the patient is needed to assess nutritional status (Fig. 83.13).

Nutritional Guidelines

Guidelines are useful, but it is important that dietary restrictions are not unnecessarily imposed and that advice is tailored to the

individual and altered as circumstances dictate. [Figure 83.14](#) summarizes the nutritional recommendations for CKD.

Hyperlipidemia

Although disturbances of lipid metabolism are commonly seen in CKD, there is a paucity of data on the effect of diet therapy in this group. A diet low in fat, particularly saturated fat, with an increased intake of soluble fiber may be helpful in reducing cholesterol level, although the role of cholesterol lowering in CKD patients is controversial (see Chapter 78). Losing weight if overweight and consuming a diet lower in sugar may improve hypertriglyceridemia, but a balance needs to be struck between healthy eating concepts and nutritional adequacy. Additional fiber, within the confines of the diet, has the benefit of helping to regulate bowel function, particularly important in PD patients.

Bone and Mineral Disorders

Guidelines for phosphorus and calcium intake as well as vitamin D type and dose in CKD have been provided by KDOQI and recently updated by the Kidney Disease: Improving Global Outcomes (KDIGO) organization (see also Chapter 81).

Vitamins, Minerals, and Trace Elements

Vitamin, mineral, and trace element abnormalities in CKD relate to dietary restriction, dialysate losses, and the necessity of intact kidney function for normal metabolism of certain vitamins. However, the dietary requirements for patients with CKD are not clear-cut.

Protein and potassium restrictions can lead to inadequate intakes of pyridoxine, vitamin B₁₂, folic acid, vitamin C, iron,

and zinc. The use of recombinant human erythropoietin may increase the requirement for iron and folic acid (see Chapter 79).

Increased serum homocysteine is a known risk factor for cardiovascular morbidity in CKD (see Chapter 78). However, lowering of serum homocysteine concentration with folic acid, vitamin B₁₂, and pyridoxine supplements has had no effect on cardiovascular outcomes in patients with advanced CKD.²⁶ A variety of multivitamin preparations are available that contain a recommended vitamin profile for dialysis patients (vitamin C, 60 mg; biotin, 300 µg; calcium pantothenate, 10 mg; cyanocobalamin, 6 µg; folic acid, 800 µg; niacinamide, 20 mg; pyridoxine, 10 mg; riboflavin, 1.7 mg; and thiamine, 1.5 mg).²⁷ In the absence of firm guidance, it is prudent to have a low threshold for commencing such a vitamin preparation. The European Best Practice Guidelines (EBPG) on nutrition give opinion-based recommendations for intakes of vitamins, minerals, and some trace elements in patients on HD.²⁸

High-dose vitamin C supplements, popular in the general population, should not be taken as they may lead to oxalosis and extensive soft tissue calcification, including blood vessels, heart, and retina. Supplementation with fat-soluble vitamins is generally not recommended (with the exception of vitamin E, which the EBPG recommend can be supplemented in HD patients for secondary prevention of cardiovascular events and prevention of recurrent muscle cramps)²⁸ because diets do not tend to be deficient, dialysis losses are minimal, and accumulation can occur.

Recommendations for mineral intakes are shown in [Figure 83.14](#).

Nutritional Recommendations in Renal Disease			
Daily Intake	Predialysis CRF	Hemodialysis	Peritoneal Dialysis
Protein (g/kg ideal BW) (see KDOQI ²⁴ for estimation of adjusted edema-free body weight)	0.6–1.0 Level depends on the view of the nephrologist 1.0 for nephrotic syndrome	1.1–1.2 ^{24, 28} This is a broad recommendation as protein intake would be individualized for the patient's nutritional status, serum phosphate levels, and dialysis adequacy	1.0–1.3 ^{24, 32}
Energy (kcal/kg BW)	35 ²⁴ (<60 yr) 30–35 ²⁴ (>60yr)	35 ²⁴ (<60 yr) 30–35 ²⁴ (>60 yr)	35 ²⁴ including dialysate calories (<60 yr) 30–35 ²⁴ including dialysate calories (>60 yr)
Sodium (mmol)	<100 (more if salt wasting)	<100	<100
Potassium	Reduce if hyperkalemic If hyperkalemic, advice will take the form of decreasing certain foods (e.g. some fruits and vegetables) and giving information about cooking methods	Reduce if hyperkalemic	Reduce if hyperkalemic; potassium restriction is generally not required
Phosphorous	Reduce; level dependent on protein intake Advice will take the form of reducing certain foods (e.g. dairy, offal, some shellfish) and giving information about the timing of binders with high phosphorus meals and snacks		
Calcium	In CKD stages 3–5, total intake of elemental calcium (including dietary calcium) should not exceed 2000 mg/day	Total intake of elemental calcium (including dietary calcium) should not exceed 2000 mg/day	Total intake of elemental calcium (including dietary calcium) should not exceed 2000 mg/day

Figure 83.14 Nutritional recommendations in chronic kidney disease. Recommendations are for typical patients but should always be individualized on the basis of clinical, biochemical, and anthropometric indices. BW, body weight; CKD, chronic kidney disease; CRF, chronic renal failure; KDOQI, Kidney Disease Outcomes Quality Initiative.

Monitoring and Treatment

Monitoring of patients with CKD involves a combination of nutritional assessment, noting relevant biochemistry (potassium, phosphate, lipids), and observation of fluid status. The challenge comes in giving advice that carefully balances control of electrolytes while not compromising nutritional status. When anorexia is present, strategies to treat this should be considered and nutrient intake maximized by use of one or more of the methods discussed in the following sections.

Enteral Supplementation

If food fortification advice is insufficient, supplements, in the form of high-protein, high-calorie drinks, powders, and puddings, should be administered. Enteral tube feeding is also an option if nutrient intake cannot be increased sufficiently by use of oral supplements. Renal-specific tube feeds and supplements are available that have lower fluid and electrolyte contents. A systematic review suggested that enteral multivitamin support increases serum albumin concentration and improves total dietary intake in patients receiving maintenance dialysis.²⁹

Supplementation of Dialysate Fluids

Intradialytic parenteral nutrition (IDPN) can be used to provide intensive parenteral nutrient therapy with use of concentrated hypertonic solutions three times weekly during HD treatments without the need for establishing a central venous line. The nutrients, usually a mixture of amino acids, glucose, and lipid, are infused into the venous blood line, and only about 10% of infused amino acids are lost into the dialysate. In 2007, a prospective, randomized trial of oral supplements with and without a year of IDPN failed to show any advantage of adding IDPN to oral supplements. However, the study did show that nutrition supplementation improved prealbumin levels, which was associated with a decrease in morbidity and mortality in malnourished HD patients.³⁰

Intraperitoneal amino acids (IPAA) are sometimes used in PD. A 1.1% amino acid solution is substituted for glucose in PD fluid, and about 80% of the amino acids are absorbed in a 4-hour period.³¹ The long-term effects of IPAA on nutritional status and clinical outcomes are not known.

KDOQI has suggested that IPAA (for PD) or IDPN (for HD) should be considered for patients who have evidence of protein or energy malnutrition and inadequate protein or energy intake and are unable to tolerate adequate oral supplements or tube feeding.²⁴

Appetite Stimulants

Megestrol acetate, a progesterone derivative, moderately improved appetite in HD patients in small studies. However, as megestrol acetate is not without its side effects, larger trials are required before recommendations can be made for CKD patients. More studies are also required for ghrelin, an orexigenic hormone, and melanocortin-receptor antagonists.

Metabolic Acidosis

Although some trials have shown no detrimental effect of mild metabolic acidosis, many others have reported that normalization of the predialysis serum bicarbonate concentration is beneficial for protein nutritional status and bone metabolism. Medical management of metabolic acidosis is discussed further in Chapter 12. Current guidelines recommend the correction of acidosis in dialysis-dependent patients.^{28,32}

Dermatologic Manifestations of Chronic Kidney Disease

Pieter Evenepoel, Dirk R. Kuypers

Cutaneous disorders are common in patients with end-stage renal disease (ESRD), with the most prevalent disorder being hyperpigmentation. Many of these cutaneous disorders are due to the underlying renal disease, whereas others relate to the severity and duration of uremia.

Skin lesions associated with cutaneous aging have a high incidence in ESRD patients, including wrinkling, senile purpura, actinic keratoses, and diffuse hair loss. The prevalence of skin cancers does not appear to be increased unless the patient had received or is receiving immunosuppression.

Improved treatments in dialysis patients have resulted in changes in the frequency and types of skin disorders observed in conjunction with ESRD. Dermatologic conditions such as uremic frost, erythema papulatum uremicum, uremic roseola, and uremic erysipeloid now rarely occur. Pigmentary alterations, xerosis, ichthyosis, half-and-half nails, acquired perforating dermatosis (Fig. 84.1), bullous dermatoses, pruritus, and calcific uremic arteriopathy are prevalent, whereas nephrogenic systemic fibrosis remains a rare entity.¹ The last four skin disorders are the focus of this chapter because they are associated with significant morbidity or mortality and represent an ongoing diagnostic or therapeutic challenge.

UREMIC PRURITUS

Clinical Manifestations

Uremic pruritus (UP) is a frequent symptom of ESRD with a reported prevalence ranging from 22% to 48%. Although its incidence in adult dialysis patients has declined as a result of improved dialysis efficacy and the introduction of so-called biocompatible dialysis membranes, pruritus remains a frustrating problem for patients, causing serious discomfort and skin damage, often in association with disturbance of day and night rhythm, sleeping disorders, depression, anxiety, and diminished quality of life.^{2,3} The intensity and spatial distribution of UP vary significantly between patients and over time throughout the course of renal disease. Excoriations, induced by uncontrollable scratching with or without superimposed infection, are frequently encountered in severely affected patients and rarely lead to prurigo nodularis, that is, a treatment-resistant lichenified or excoriated papulonodular chronic skin eruption (Fig. 84.2). The most frequently involved body areas are the back, limbs, chest, and face; 20% to 50% of patients complain of generalized pruritus.⁴

Pathogenesis

Many uremic factors are thought to contribute to UP. Parathyroid hormone (PTH) and divalent ions (calcium, phosphate, and magnesium) have been implicated as itching is a frequent

symptom accompanying severe secondary hyperparathyroidism and elevated calcium-phosphate product. However, the lack of consistent correlations between serum and skin levels of PTH, calcium, phosphorus, and magnesium with the severity of UP indicates that other factors contribute to its development. Histamine released by mast cells has been implicated in UP. The number of dermal mast cells is increased in uremic patients, and higher tryptase and histamine plasma concentrations are reported in severe cases. Histamine release is triggered by substance P, a neurotransmitter involved in itch sensation. The role of elevated serotonin (5-hydroxytryptamine [5-HT₃]) levels in dialysis patients with UP is debated as clinical trials using a selective inhibitor of 5-HT₃ have yielded conflicting results (see later discussion). Xerosis is a common skin problem (60% to 90%) in dialysis patients that predisposes to UP. Skin dryness is caused by primary dermal changes associated with uremia, such as atrophy of sweat glands with impaired sweat secretion, disturbed stratum corneum hydration, sebaceous gland atrophy, and abnormal arborization of free cutaneous nerve fiber endings.

There are two major hypotheses of the mechanisms of UP. The opioid hypothesis proposes that UP is caused by overexpression of opioid μ receptors in dermal cells and lymphocytes. Consistent with this hypothesis, activation of the κ opioid system using a κ -receptor agonist was efficient in reducing pruritus in a mouse model. In contrast, the immune hypothesis considers UP an inflammatory systemic disease rather than a local skin disorder. Studies examining the beneficial effects of ultraviolet B (UVB) exposure on pruritus showed that UVB attenuates the development of Th1-type lymphocytes in favor of the Th2 type. Indeed, the number of CXCR3-expressing and interferon- γ -secreting CD4⁺ cells (indicating Th1 differentiation) is significantly increased in the circulation of dialysis patients with pruritus compared with those without. Serum markers of inflammation, such as C-reactive protein and interleukin-6, are also higher in subjects with UP.

Treatment

Common causes of UP in chronic kidney disease (CKD) and dialysis patients like primary skin disorders (e.g., urticaria, psoriasis, atopic dermatitis), liver disease (e.g., hepatitis), and endocrine diseases (e.g., hypothyroidism, diabetes mellitus) should be ruled out and adequately treated. The treatment approach to UP is shown in Figure 84.3.

Optimizing Dialysis Therapy

Improving both dialysis efficacy and the nutritional status of the dialysis patient will result in a reduced prevalence and severity of UP. The use of so-called biocompatible hemodialysis (HD) membranes also has a beneficial effect. Adequate control of

Figure 84.1 Cutaneous disorders in patients with end-stage renal disease. **A**, A spectrum of pigmentary alterations occurs in dialysis patients, brownish hyperpigmentation in sun-exposed areas being the most prevalent. **B**, Xerosis, a dry or roughened skin texture, is seen in up to 75% of dialysis patients. **C**, Half-and-half nails (also termed red and white nails) occur in as many as 40% of patients on dialysis. The nails exhibit a whitish or normal proximal portion and an abnormal brown distal portion. **D**, Acquired perforating dermatosis affects approximately 10% of the dialysis population. The lesion is usually asymptomatic and consists of grouped dome-shaped papules and nodules, 1 to 10 mm in diameter. The trunk and the extremities are most commonly involved.

calcium and phosphorus plasma concentrations by short-term use of dialysate with low calcium and magnesium concentrations ameliorated pruritus symptoms in only a few small studies and may lead to worsening of renal osteodystrophy in cases of prolonged use. Parathyroidectomy is not advocated for relief of UP because no consistent beneficial effects have been demonstrated.

Skin Emollients

The application of emollients is probably still the primary therapeutic action undertaken by many nephrologists despite contradictory results in the literature. The use of simple emollients

without perfumes or other additives is preferred. Continuous bath oil therapy containing polidocanol, a mixture of monoether compounds of lauryl alcohol and macrogol, seems to be of value for some patients.

Antihistaminic Drugs

Classic antihistamines have limited efficacy and do not differ in efficacy compared with emollients; newer, second-generation antihistamines might have some effect but have not been formally tested in UP. Ketotifen (2 to 4 mg/day), a putative mast cell stabilizer, was beneficial in one small study.

Phototherapy

UV light, especially UVB (wavelength, 280 to 315 nm), is effective for treatment of UP and is well tolerated except for occasional sunburn. The duration of the antipruritic effect of thrice-weekly total body UVB therapy (total, 8 to 10 sessions) is variable but may last for several months. Potential carcinogenic effects of UV radiation require serious consideration, and its prolonged use is contraindicated in patients with a fair complexion (skin phototypes I and II).

5-Hydroxytryptamine Antagonist

Ondansetron, a selective 5-HT₃ antagonist, was used successfully in a small study in peritoneal dialysis patients. However, a subsequent larger randomized, placebo-controlled study failed to show superiority over placebo in HD patients.

Figure 84.2 Prurigo nodularis. (Courtesy I. Macdougall, London, UK.)

Opioid Receptor Antagonists and Agonists

The oral μ opiate receptor antagonist naltrexone seemed effective for the treatment of UP in a small randomized, crossover trial in 15 dialysis patients. In a subsequent larger trial, a significant difference in efficacy could not be demonstrated between 4 weeks of treatment with naltrexone (50 mg/day) or placebo. More recently, a κ -receptor agonist, nalfurafine, given intravenously after HD, was tested in two randomized, double-blind, placebo-controlled trials comprising 144 patients. Itching intensity, excoriations, and sleep disturbances were significantly reduced in patients receiving the active compound without an excess of drug-related side effects compared with placebo.⁵ In some patients, symptom relief between dialysis sessions was incomplete, and central nervous system side effects such as drowsiness, dizziness, and somnolence occurred.

Gabapentin

Gabapentin, an anticonvulsant drug, administered after dialysis (300 mg) was effective in reducing pruritus. A reduced dose is required if it is given chronically to subjects with ESRD as it has a narrow therapeutic window, and it can accumulate and cause neurotoxic side effects.⁶

Immunomodulators and Immunosuppressive Agents

A 7-day course of thalidomide reduced the intensity of UP by up to 80% in a placebo-controlled crossover study of 29 HD patients. Because of its strong teratogenic properties, thalidomide should probably be reserved for therapy-resistant severe UP in individuals outside the reproductive-age category. Adverse effects of thalidomide, such as peripheral neuropathy and cardiovascular side effects, limit its continuous longer use. A prospective, single-center study of 25 chronic dialysis patients with UP demonstrated that 6 weeks of treatment with tacrolimus ointment (0.1%) significantly reduced the severity of UP. Tacrolimus

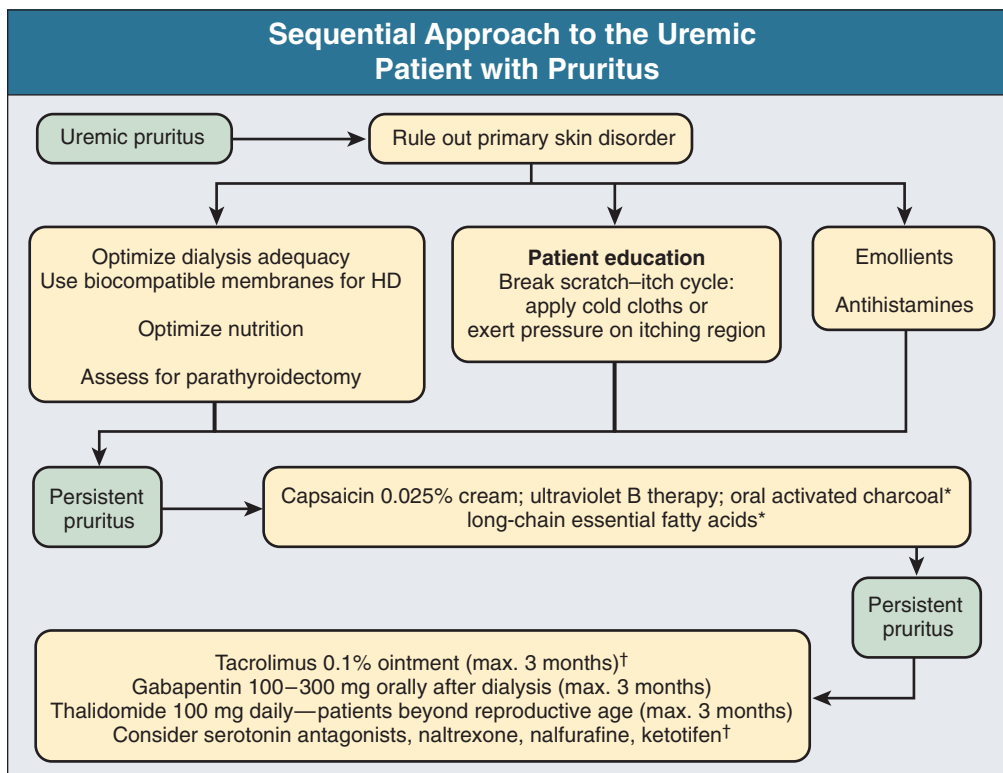

Figure 84.3 Sequential approach to the uremic patient with pruritus. *See text for details. †Therapeutic benefit in studies has been described variably; see text for details. HD, hemodialysis.

mus was well tolerated in this trial and caused no detectable systemic exposure or side effects.⁷ However, a subsequent smaller vehicle-controlled trial showed equal relief of UP with vehicle and tacrolimus. The risks of long-term topical use of these agents are currently unknown, and their prolonged use is not recommended until more data are available.

Long-Chain Essential Fatty Acids

Oral administration of γ -linoleic acid (GLA)-rich primrose oil resulted in significant improvement of UP in chronic dialysis patients. Supplementation of GLA-rich primrose oil is thought to augment synthesis of anti-inflammatory eicosanoids. Similar effects could be obtained by use of fish oil, olive oil, and safflower oil.

Capsaicin

Capsaicin (*trans*-8-methyl-*N*-vanillyl-6-nonenamide) is a natural alkaloid found in the pepper plant that depletes the cutaneous type C sensory nerve endings of substance P. Two clinical studies showed that application of a 0.025% capsaicin cream significantly alleviated UP in dialysis patients while exhibiting no side effects.

Oral Activated Charcoal

Pruritus symptoms completely disappeared or were significantly reduced in chronic dialysis patients treated with activated charcoal (6 g/day) for 8 weeks. In two different clinical studies, comparable results were obtained with this inexpensive and well-tolerated compound, rendering it a valuable alternative for patients with UP.

Miscellaneous

Various other types of therapies have been examined in the treatment of pruritus but are, despite the effectiveness of some, not considered first choice in chronic HD patients because of undesirable side effects, cumbersome use, or incompatibility with renal replacement therapy (sauna, cholestyramine, nicergoline). Others that have not reduced UP in a controlled setting and are therefore not advocated include acupuncture, low-protein diet, intravenous lidocaine, and mexiletine.

BULLOUS DERMATOSES

Bullous dermatoses are reported in up to 16% of patients on maintenance dialysis. They can be subdivided into true porphyrias (e.g., porphyria cutanea tarda [PCT], variegate porphyria), pseudoporphyrias (e.g., secondary to nonporphyrinogenic drugs and chemicals, dialysis-porphyria), and other photodermatoses.⁸ They are clinically and histologically similar and are characterized by a blistering photosensitive skin rash. The dorsal hands and the face are the most affected areas (Fig. 84.4).

PCT is caused by abnormalities in the porphyrin-heme biosynthetic pathway leading to an accumulation of highly carboxylated uroporphyrins in the plasma and skin. Phenotypic expression of the disease also requires one or more of a number of external contributory factors, including alcohol, estrogens, iron, and infection with hepatitis B and C. It is important to distinguish PCT from other porphyrias in which patients are at risk for development of potentially fatal neurologic attacks if they are exposed to porphyrinogenic drugs and other precipitants. Therapeutic options include avoidance of environmental triggers, HD with high-flux membranes, repeated small-volume phlebotomies, and iron chelators.

Figure 84.4 Porphyria cutanea tarda. Tense bullae, erosions, and crusts of the dorsal hands. (From reference 9.)

Figure 84.5 Benign nodular calcification (calcinosis cutis). Firm subcutaneous nodule adjacent to the elbow.

The term *pseudoporphyria* was originally used for patients with normal plasma porphyrins who exhibited PCT-like skin lesions secondary to drugs and chemicals. However, some dialysis patients also develop similar skin lesions that spontaneously heal and leave a hypopigmented area; this entity is known as dialysis-porphyria; a proportion of these have raised plasma porphyrins but without the disturbances in porphyrin metabolism classically found in the porphyrias. In rare patients, an offending medication can be identified. However, in most dialysis patients, protection from sun exposure appears to be the only preventive measure.

CALCIFIC UREMIC ARTERIOLOPATHY (CALCIPHYLAXIS)

Definition

Calcific uremic arteriolopathy (CUA), or calciphylaxis, is a devastating and life-threatening ischemic vasculopathy confined primarily to patients with CKD. There are also reports of this disease in nonuremic patients. The ischemia may be so severe that frank infarction of downstream tissue develops. The most common and most noticeable damage is in the skin and subcutaneous tissues.¹⁰ CUA should be distinguished from benign nodular calcification (calcinosis cutis; Fig. 84.5), which can develop in patients with very high serum calcium-phosphate product.

Pathogenesis

The pathogenesis of CUA involves abnormalities in mineral metabolism in uremia that predispose to vascular and soft tissue calcification, but no single abnormality is sufficient to predict the development of this disorder. Elevated levels of PTH and therapy with vitamin D analogues have been associated with an increased risk of CUA, although the evidence is not always striking. A perturbation of the calcium and phosphate homeostasis most probably underlies the positive association. Insufficient activation or expression of inhibitors of calcification should also be considered in the pathogenesis. Inhibitors of vascular calcification include matrix GLA protein (MGP), osteoprotegerin, pyrophosphate, and fetuin-A. MGP requires vitamin-K mediated γ -carboxylation for its functional activity. As a consequence, coumarin anticoagulants and vitamin K deficiency may antagonize MGP function and stimulate vascular calcification. Levels of both osteoprotegerin and fetuin-A decline with inflammation. Finally, several lines of evidence indicate that a hypercoagulable state secondary to an absolute or functional protein C or protein S deficiency may be involved in the pathogenesis of CUA.¹⁰

Epidemiology and Risk Factors

Although hard epidemiologic data are lacking, the incidence of CUA may be increasing. This might be due in part to increased physician awareness and possibly the practice of treating severe hyperparathyroidism with calcium-based phosphate binders plus vitamin D analogues. The estimated incidence ranges between 1 and 4 per 100 patient-years.

Female gender, Caucasian race, obesity, diabetes, use of coumarin anticoagulants, and dialysis vintage are established risk factors. Probable risk factors include low serum albumin concentrations, the use of calcium salts and vitamin D analogues, and exposure to high doses of iron salts. There is no correlation between the severity of any of these factors and the development of CUA.¹⁰

Clinical Manifestations

CUA is frequently precipitated by a specific event, such as local skin trauma or a hypotensive episode. CUA is typically characterized by areas of ischemic necrosis of the dermis, subcutaneous fat, and, less often, muscle. These ischemic changes lead to livedo reticularis or violaceous, painful, plaque-like subcutaneous nodules on the trunk, buttocks, or proximal extremity, that is, in areas of greatest adiposity (proximal CUA; Fig. 84.6A). The early purpuric plaques and nodules progress to ischemic or necrotic ulcers with eschars that often become infected. CUA can also affect the hands, fingers, and lower extremities, thereby mimicking atherosclerotic peripheral vascular disease (distal CUA; Fig. 84.6B). Peripheral pulses are preserved distal to the area of necrosis. Myopathy, hypotension, fever, dementia, and infarction of the central nervous system, bowel, or myocardium have been described in association with cutaneous necrosis. This condition is termed systemic CUA.^{10,11}

Pathology

The histologic features of CUA are suggestive but not pathognomonic. Specimens from incisional biopsies of early lesions show subtle histologic changes. Late lesions characteristically show epidermal ulceration, dermal necrosis, and mural calcifica-

tion with intimal hyperplasia of small and medium-sized blood vessels in the dermis and subcutaneous tissue (Fig. 84.7).

Diagnosis and Differential Diagnosis

Many clinicians base the diagnosis of CUA on physical examination findings only. Although ulceration is an obvious presentation of CUA, increasing awareness of the condition should allow diagnosis at an earlier, nonulcerative stage.¹¹ Biopsies are discouraged because of potential ulceration in the region of the incision and the risk of sample error. Other potentially useful diagnostic procedures include measurements of transcutaneous oxygen saturation, bone scintigraphy (Fig. 84.8), and xeroradiography.¹¹

The following conditions should be considered in the differential diagnosis: systemic vasculitis, peripheral vascular disease, pyoderma gangrenosum, atheroemboli, cryoglobulinemia, warfarin-induced skin necrosis, and systemic oxalosis. Considering these risks, a skin biopsy should be performed only when clinical circumstances do not suggest CUA or when detailed clinical and technical examinations, including the assessment of coagulation and immunologic parameters, point to an alternative diagnosis.

Natural History

Despite intensive combined treatments, the prognosis of CUA remains poor; the overall 1-year survival is 45% and the 5-year survival is 35%, with a relative risk of death of 8.5 compared with other dialysis patients. Patients with ulcerative or proximal CUA have the worst prognosis. Infection accounts for up to 60% of the mortality.¹¹

Prevention and Treatment

Preventive approaches include attention to calcium, phosphorus, PTH homeostasis, and nutritional state. Specific therapeutic regimens have been limited to uncontrolled case series (Fig. 84.9). A reasonable plan of intervention should include an aggressive program of wound care and prevention of superinfection, adequate pain control, and correction of underlying abnormalities in plasma calcium and phosphorus concentrations. This includes cessation of vitamin D supplementation, intensification of the dialysis treatment, and use of a low-calcium dialysate and non-calcium-containing phosphate binders (e.g., sevelamer, lanthanum carbonate). Furthermore, local tissue trauma, including subcutaneous injections, should be avoided. Parathyroidectomy is effective in the control of CUA in some series but not in others and should be reserved for patients with severe hyperparathyroidism.¹⁰ In such patients, calcimimetic agents may be a suitable noninvasive alternative. Vitamin K supplementation is advised in patients with coumarin-associated CUA. Novel and experimental therapies include hyperbaric oxygen therapy and bisphosphonates. Sodium thiosulfate has repeatedly been used to enhance the solubility of calcium deposits¹² because exchange of calcium for sodium results in extremely soluble calcium thiosulfate. Besides being a chelator of calcium, sodium thiosulfate is also a potent antioxidant. Sodium thiosulfate is given intravenously at the end of every HD session (12.5 to 25 g during 30 to 60 minutes). Apart from nausea and vomiting, the therapy is well tolerated. The major side effect of sodium thiosulfate infusion is the development of metabolic acidosis. The optimal duration of treatment and potential effects of long-term treatment on bone are unknown.

NEPHROGENIC SYSTEMIC FIBROSIS

Definition

Nephrogenic systemic fibrosis (NSF), formerly known as nephrogenic fibrosing dermopathy, is a scleroderma-like fibrosing disorder that develops in the setting of renal failure. The fibrotic process affects the dermis, subcutaneous tissues, fascia, and other organs, including striated muscles, heart, and lungs.^{13,14}

Pathogenesis

The role of gadolinium-based contrast (GBC) agents in the development of NSF is increasingly recognized; exposure to gadolinium before the onset of disease was confirmed in more than 95% of reported cases. Free gadolinium ions are highly toxic to tissues. The toxic effects of gadolinium are circumvented by sequestration of the metal by chelates, large organic molecules

that form a stable complex with gadolinium and make the ion biochemically inert and nontoxic. Under normal circumstances, GBC agents are eliminated by the kidney through glomerular filtration. Evidence points toward aberrant activation of circulating fibrocytes as a central event in the genesis of NSF. Other investigators have suspected that the strongly profibrotic mediator transforming growth factor β may be involved in the pathogenesis of NSF.

Epidemiology

NSF is a rare disorder. Since the identification of the first cases of NSF in 1997, the NSF registry has confirmed more than 215 cases from medical centers worldwide. NSF equally affects men and women. The risk for development of NSF after GBC agent exposure is related to the degree of renal failure and stability of the chelate. Gadodiamide (marketed as Omniscan in the United States), the linear nonionic chelate-based formulation, maintains

Figure 84.8 Bone scintigraphic abnormalities in calcific uremic arteriolopathy. Calf calcification in a patient with gross ulcerations in both legs from the popliteal fossae to the ankles (arrows). (From reference 15.)

Treatment Options in Patients with CUA

1. Reduction of pro-calcifying factors

- Intensified (e.g., daily, hemodialysis; switch from peritoneal dialysis to hemodialysis; low-calcium dialysate)
- Avoidance of vitamin D and calcium supplements; administration of calcium-free phosphate binders; bisphosphonate administration (caution if adynamic bone disease is suspected)
- Parathyroidectomy (in case of hyperparathyroidism) or administration of cinacalcet

2. Improving the status of calcification inhibitors

- Halt vitamin K antagonists (warfarin)
- Aggressive treatment of infections or other proinflammatory stimuli to increase fetuin-A levels (a negative acute-phase protein)
- Experimental:
Administration of high-dose vitamin K₂?
Administration of fetuin-A (e.g., by fresh frozen plasma or plasma exchange?)

3. Prevention or reversal of calcium-phosphate precipitation

- Administration of sodium thiosulfate

4. Supportive measures

- Avoidance of additional local tissue trauma by atraumatic wound care with gentle debridement of necrotic tissue and avoidance of subcutaneous injections
- Improving oxygen supply by hyperbaric oxygen therapy
- Anticoagulation (heparin and low-molecular-weight heparins)
- Adequate pain management
- Adequate infection control

Figure 84.9 Treatment options in patients with CUA (calciophylaxis). Theoretical options, based on pathophysiologic considerations, which have not been tested in clinical practice, are printed in italics. (Modified from reference 12.)

the highest risk on the basis of epidemiologic data and animal studies. Gadopentetate, the linear ionic chelate-based product, probably has a medium risk, less than linear nonionic chelates but more than macrocyclic chelates. Other factors reported to be associated with NSF (without definitive proof) include coagulation abnormalities and deep venous thrombosis, recent surgery (particularly vascular surgery), hyperphosphatemia, and the use of high doses of recombinant erythropoietin. Angiotensin-converting enzyme (ACE) inhibitors might protect against NSF.

Clinical Manifestations and Natural History

The lesions of NSF are typically symmetric and develop on limbs and trunk. A common location is between the ankles and mid thighs and between the wrists and mid-upper arms bilaterally. On occasion, swelling of the hands and feet, sometimes associated with bullae, is noted. The primary lesions are skin-colored to erythematous papules that coalesce into erythematous to brawny plaques with a peau d'orange appearance (Fig. 84.10A). These plaques have been described as having an ameboid advancing edge. Nodules are sometimes also described. Involved skin becomes markedly thickened and woody in texture. Joint contractures may develop rapidly, with patients becoming wheelchair dependent within days to weeks of onset (Fig. 84.10B). Patients often complain of pruritus, causalgia,

Figure 84.10 Nephrogenic systemic fibrosis. **A**, Peau d'orange appearance. **B**, Swelling of the hands, accompanied by palmar erythema, blisters, and contracture of the fingers.

and sharp pains in the affected areas.¹³ In almost all cases of NSF, the disease course parallels the course of the underlying renal dysfunction. Although NSF has not been reported as a cause of death, the impairment of mobility seen in this disorder has led to fractures that ultimately resulted in a protracted hospital course and death.

Pathology

The histopathologic changes in affected skin include marked proliferation of spindle cells, the presence of numerous dendritic cells, and accumulation of mucinous material and thick collagen bundles (Fig. 84.11). Most dermal spindle cells in NSF have the

Figure 84.11 Histopathologic features of nephrogenic systemic fibrosis. Haphazardly arranged dermal collagen bundles with surrounding clefts and a strikingly increased number of similarly arranged spindled and plump fibroblast-like cells.

immunophenotype of a circulating fibrocyte, a recently characterized circulating cell that expresses markers of both connective tissue cells and circulating leukocytes. Metastatic calcification and NSF may be found in the same lesion.

Diagnosis and Differential Diagnosis

The gold standard of diagnosis is histopathologic examination of skin biopsy specimens from an involved site. Skin lesions can also be visualized by [¹⁸F]-fluorodeoxyglucose whole-body positron emission tomography. NSF resembles other fibrosing skin disorders including scleromyxedema, scleroderma, eosinophilic fasciitis, eosinophilia-myalgia syndrome, and Spanish toxic oil syndrome. The specific distribution of cutaneous involvement, the occurrence in the setting of renal failure, and the unique histopathologic features distinguish NSF from the other fibrotic disorders.

Treatment and Prevention

There is no consistently effective therapy for NSF. There is variable evidence for the efficacy of plasma exchange. Other therapeutic modalities that have been used (or are under investigation) include imatinib, oral and topical corticosteroids, selective histamine blockade, calcipotriene ointment, cyclophosphamide, cyclosporine, thalidomide, interferon alfa, photophoresis, and PUVA (psoralen ultraviolet A) therapy. Intense physiotherapy is advised in every patient to prevent or to reverse limb disability related to contractures of the joints.¹³ At present, prevention of NSF seems more important than any of the currently available interventions, and widespread clinical awareness of this condition is required. Avoidance of GBC agents in high-risk patients (acute kidney injury [AKI] and subjects with CKD with an estimated glomerular filtration rate <30 ml/min per 1.73 m²) is the best measure to prevent this catastrophic complication. If GBC agent exposure is required, use of the smallest dosage of a macrolytic chelate is strongly advised. HD (three sessions within 48 hours) should be considered after GBC agent exposure in patients who are already on this modality.

Acquired Cystic Kidney Disease and Malignant Neoplasms

Frank Eitner

DEFINITION

Acquired cystic kidney disease (ACKD) was first recognized in 1847 by John Simon in patients with chronic Bright's disease. He described the development of cystic renal changes with cysts ranging from "mustard seed to as large as cocoa nuts" and also noted that they "run a slow and insidious progress during life, and often leave in the dead body no such obvious traces as would strike the superficial observer." ACKD was "rediscovered" by Dunnill and colleagues¹ in 1977 in kidneys from dialysis patients.

ACKD is a disease of chronic renal failure of any etiology and has to be differentiated from other types of cystic kidney disease (see Chapters 44 and 45). It is usually defined as more than three to five macroscopic cysts in each kidney of a patient who does not have a hereditary cause of cystic disease. ACKD is associated with renal neoplasms with such high frequency that some authors consider ACKD preneoplastic.²

PATHOGENESIS

Most cysts are lined by a single layer of epithelium composed of flat nondescript cells, cells with abundant cytoplasm and hyaline droplets, or small cuboidal cells resembling those from distal tubules or collecting ducts.² Others have argued that the presence of a brush border on the luminal membrane suggests that the cysts arise primarily from proliferation of proximal tubular epithelial cells. Although the mechanisms of tubule transformation into cysts are not entirely clear, tubular epithelial cell hyperplasia is currently viewed as a central early event in ACKD pathogenesis (Fig. 85.1).³ Various factors have been implicated in the development of tubular hyperplasia, including plasticizer, ischemia, and uremic metabolites. However, the most important factor appears to be slow, progressive parenchymal loss, which could explain why the development or progression of ACKD does not appear to be influenced by the type of underlying renal disease or the choice of dialysis modality. The loss of intact nephrons is a strong stimulus for compensatory growth of the remaining, still intact nephrons, which is achieved by initial hypertrophy and later by hyperplasia. In these hyperplastic tubules, a cyst will develop if transepithelial fluid secretion continues, and if it is due to anatomic distortion or obstruction, the distal outflow is impaired.

With the continuing presence of mitogenic stimuli, the epithelial layer of the cyst becomes multilayered and atypical cells form intracystic papillary structures or mural adenomas. Activation of proto-oncogenes, chromosomal abnormalities, and

additional factors such as genetic background, environmental chemicals, and sex hormones thereafter probably account for the transition of the proliferative process into malignant growth (see Fig. 85.1).³

EPIDEMIOLOGY

Among patients entering dialysis treatment, prevalences of ACKD ranging from 5% to 20% have been described. ACKD can occur in some patients even before dialysis is initiated. In both chronic hemodialysis and peritoneal dialysis patients, prevalence then increases at a similar rate and reaches 80% to 100% after 10 years of treatment (Fig. 85.2).³⁻⁵ Children are also prone to the development of ACKD. Several but not all studies have reported an increased frequency or faster progression in men than in women. The rate of progression appears to slow after 10 to 15 years of dialysis.

The frequency of ACKD as well as of renal tumors in dialysis patients may be underestimated on the basis of imaging methods alone. Renal cysts are detectable by ultrasound with a minimum size of 0.5 cm. Data obtained in 260 native nephrectomy specimens at the time of transplantation with a median dialysis duration of 1.0 year identified ACKD in 33%, renal adenomas in 14%, and renal cell carcinomas (RCCs) in 4% of the cases.⁶

CLINICAL MANIFESTATIONS

ACKD can be manifested as unilateral or bilateral cysts, which are mostly cortical and variable in size and number. Rarely, severe ACKD can become macroscopically indistinguishable from adult polycystic kidney disease (PKD). In contrast to hereditary cystic diseases, the cysts of ACKD are strictly confined to the kidneys. The disease is usually asymptomatic and discovered accidentally during abdominal imaging procedures. Alternatively, it may be manifested by potential complications or consequences of ACKD:

- Cystic hemorrhage with or without hematuria; bleeding may occur with cyst rupture with subsequent perinephric hemorrhage or retroperitoneal hemorrhage, which may in rare cases be severe enough to lead to hypovolemic shock.
- Calcifications in or around cysts and in rare cases stone formation (calcium-containing stones or β_2 -microglobulin stones).
- Cyst infection, abscess formation, or sepsis.
- Erythrocytosis in advanced cases, similar to erythrocytosis observed in polycystic kidney disease.
- Malignant transformation.⁷

Figure 85.1 Pathogenesis of acquired cystic kidney disease (ACKD) and associated renal cell carcinoma. Diagram of events leading to the development of ACKD and subsequent malignant transformation. (Modified from reference 3.)

Figure 85.2 Prevalence of acquired cystic kidney disease (ACKD) in hemodialysis patients. Summary of reported ACKD prevalences in chronic hemodialysis patients in relation to the length of hemodialysis treatment. Four separate studies are shown.

Acquired Cystic Kidney Disease–Associated Renal Cell Carcinoma

Malignant transformation, the most feared complication of ACKD, accounts for about 80% of the renal cell neoplasms observed in uremic patients. In an unselected series of chronic

dialysis or transplant patients, the cumulative incidence of RCC complicating ACKD is probably below 1%, although rates up to 7% have been reported in some small studies. These data indicate an up to 40-fold increased risk for RCC in ACKD patients compared with RCC in the general population. Risk factors include male gender (male-to-female ratio, 7:1), African American ethnicity, long duration of dialysis, and severe ACKD with marked organ enlargement. It is unknown whether the risk of malignant transformation differs between hemodialysis and peritoneal dialysis patients. However, cases of malignant transformation in patients treated exclusively with peritoneal dialysis have been described.

About 85% of ACKD-associated RCCs are asymptomatic. The remaining cases mostly are manifested with bleeding, usually gross hematuria, from the tumor. In cases in which nephrectomy had to be performed in dialysis patients for intractable hematuria, RCCs, not visualized before surgery, were diagnosed in about one third of the patients.

Compared with sporadic RCCs, ACKD-associated RCCs are characterized by younger age of the patient, male predominance, more frequent multicentric and bilateral manifestation, and less frequent metastases.²

PATHOLOGY

Cystic changes in ACKD are typically bilateral but may vary between kidneys. Most ACKD kidneys are smaller than normal. An increase in size above normal can be observed in cases of cyst

hematoma formation or malignant transformation. The cysts are usually restricted to the renal cortex. The size of the cysts ranges from microscopic to about 2 cm; about 60% of the cysts are smaller than 0.2 cm.² Preneoplastic changes can be detected in ACKD kidneys, including atypical cyst-lining cells forming multiple cell layers and intracystic nodular formations.

Up to 25% of kidneys with ACKD harbor tumors, about one third of which are carcinomas. RCCs arising from ACKD are multicentric in about 50% of cases, bilateral in about 10%, and papillary as well as clear cell carcinoma by histology. Transitional cell carcinoma has been reported in ACKD, occasionally in addition to the presence of RCC. However, ACKD does not seem to increase the risk for transitional cell carcinoma. Rather, its development may be related to analgesic nephropathy as the underlying renal disease, although this notion remains speculative so far.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The diagnostic approach to ACKD usually involves ultrasound (Fig. 85.3), which is a sensitive means of detecting ACKD or

large RCCs.^{4,8} However, the differentiation between simple cysts and renal carcinomas can be difficult given the echogenicity of end-stage kidney parenchyma and the complexity of cysts in ACKD. Computed tomography (CT) scanning, in particular with early contrast enhancement, is superior to ultrasound in detecting small malignant lesions (see Fig. 86.3).^{4,8,9} A classification of renal cysts (Fig. 85.4) based on their appearance in CT scans, introduced by Bosniak, is now widely accepted and is also applied to ultrasound and magnetic resonance imaging (MRI).¹⁰ Criteria that favor the diagnosis of RCC as opposed to a simple cyst include thickened and irregular walls, the presence of septa or renal tissue within the lesions, contrast enhancement, multilocularity, and large size (>4 cm). Given the risk for the development of nephrogenic fibrosis, gadolinium-enhanced MRI cannot currently be recommended for dialysis patients and renal transplant patients with a glomerular filtration rate (GFR) below 60 ml/min. The diagnostic value of MRI without contrast enhancement in this setting is not well defined. Fine-needle aspiration may be necessary to clarify equivocal findings.¹¹ However, even with all these imaging techniques, RCCs (up to 8 cm) have been missed in severely distorted kidneys.

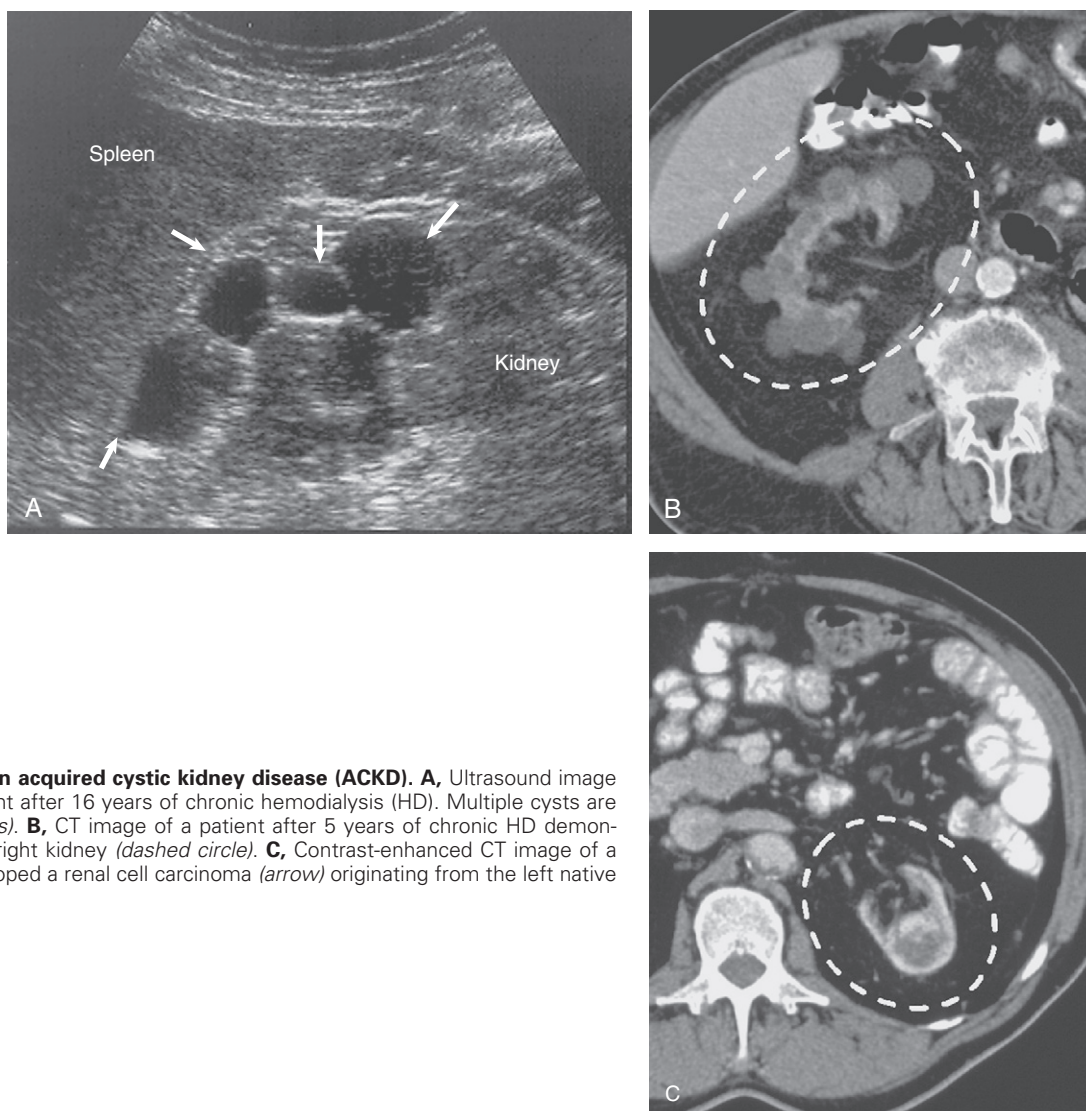

Figure 85.3 Imaging studies in acquired cystic kidney disease (ACKD). **A**, Ultrasound image of the left native kidney of a patient after 16 years of chronic hemodialysis (HD). Multiple cysts are present in the renal cortex (arrows). **B**, CT image of a patient after 5 years of chronic HD demonstrating multiple cysts within the right kidney (dashed circle). **C**, Contrast-enhanced CT image of a renal transplant patient who developed a renal cell carcinoma (arrow) originating from the left native kidney with ACKD (dashed circle).

Renal Cyst Classification System		
Category	Synonymous	Description
I	Benign simple cyst	Hairline thin cyst wall; no septa; no calcifications; no solid components; no contrast enhancement
II	Benign cyst	Minimal regular thickening of the cyst wall; few, hairline thin septa; smooth, hairline thin calcifications in wall or septa; no contrast enhancement
IIF	Moderately complex cyst	Minimal regular thickening of the cyst wall; multiple, minimal smooth thickening septa; thick, nodular calcifications in wall or septa; no contrast enhancement
III	Indeterminate cystic mass	Irregular thickening of cyst wall; multiple, measurably thick, irregular septa; thick, nodular, irregular calcifications in wall or septa; contrast enhancement present
IV	Clearly malignant cystic mass	Gross irregular thickening of cyst wall; irregular gross thickening of septa; thick, nodular irregular calcifications in wall or septa; contrast enhancement present in tissue and cysts

Figure 85.4 Renal cyst classification system. (Modified from reference 12.)

Because of the risk of malignant transformation, screening for ACKD on a regular basis, as well as regular follow-up imaging in cases of established ACKD, has been advocated. A proposal for ACKD and tumor screening is outlined in Figure 85.5. However, there is at present no consensus on screening strategies. This is because of the cost of screening as well as the risk-benefit ratio of nephrectomy in dialysis patients. A decision analysis⁵ concluded that screening for ACKD (by either ultrasound or CT scanning) in young patients with a life expectancy of 25 years offers as much as a 1.6-year gain in life expectancy. This is similar to the gain obtained in young healthy people who stop smoking. In contrast, in ACKD patients older than 60 years, no significant gain in life expectancy is achieved by regular screening.³ In a different analysis of 797 dialysis patients who had developed RCCs (90% identified by screening, 10% by clinical symptoms), screening provided a mean survival benefit of 3.3 years after adjustment for age and dialysis vintage.¹³ Screening during transplant evaluation by ultrasound followed by CT in the case of suspicious lesions is recommended on the basis of recent data showing a prevalence of renal cancer in up to 4% of the patients and concerns about the role of immunosuppression in accelerating tumor growth.¹⁴

NATURAL HISTORY

Cystic dilations of renal tubules develop microscopically once the creatinine clearance falls below 70 ml/min.¹⁵ Macroscopic cysts start to develop when serum creatinine rises above 3 mg/dl (264 μ mol/l). As discussed before, ACKD thereafter progresses and reaches a prevalence of nearly 100% after more than 10 years of dialysis (see Fig. 85.2). In malignant transformation, tumor growth rates are highly variable. The incidence of metastases at diagnosis (15% to 30% of cases) and 5-year survival rates (35%) are comparable to those observed in RCC in the general population. Death is usually associated with widespread metastases and accounts for about 2% of the deaths in renal transplant patients.

After renal transplantation, the course of ACKD is variable. There may be retardation of the progressive course of the disease or regression of the cysts, particularly if good long-term graft function is maintained. However, especially in grafts with impaired or failing renal function, there may be further

progression in the native kidneys as well as the development of *de novo* ACKD in the graft. It is not established whether renal transplantation affects the natural history of RCC complicating ACKD, although immunosuppression has been suggested as a risk factor for RCC in transplant patients with ACKD.⁷ A prospective, single-center ultrasound screening of the native kidneys in 561 renal transplant recipients identified ACKD in 23%.¹⁶ The mean duration of dialysis was 4 to 5 years, and the mean time after transplantation was 9 years. In this cohort, ACKD was slightly less frequent than had been reported in dialysis patients, possibly indicating that renal transplantation might inhibit the development of ACKD.¹⁶ The prevalence of RCCs among all 561 patients was 4.8%. However, among the patients with ACKD, RCCs were detected in almost 20%, whereas among the patients without ACKD, RCCs were detected in only 0.5%.¹⁶

TREATMENT

Treatment of ACKD is warranted only when complications such as hemorrhage, cyst infection, or malignant transformation develop. Whereas the first two complications may be handled conservatively and only rarely require surgery, malignant transformation should raise the question of nephrectomy. Given the perioperative morbidity and mortality of nephrectomy, in particular in multimorbid dialysis or transplant patients, it is not surprising that the threshold for surgical intervention in cases of RCC is still controversial.

Most authors agree that tumors larger than 3 cm in diameter justify nephrectomy because above this size, RCCs in the general population frequently metastasize (see Fig. 85.5).⁷ However, this strategy is based on an extrapolation from otherwise healthy persons, and a more aggressive approach may be required under certain circumstances. This is particularly true because tumor size in ACKD is often difficult to establish by imaging studies (given its frequent multilocular development) and because metastases have been described in ACKD even when renal tumors were not detected by imaging studies.

In the case of tumors of less than 3 cm in diameter with no complications, the slow tumor growth may justify observation with repeated imaging studies (see Fig. 85.5). Patients with high life expectancy or patients listed for transplantation might be

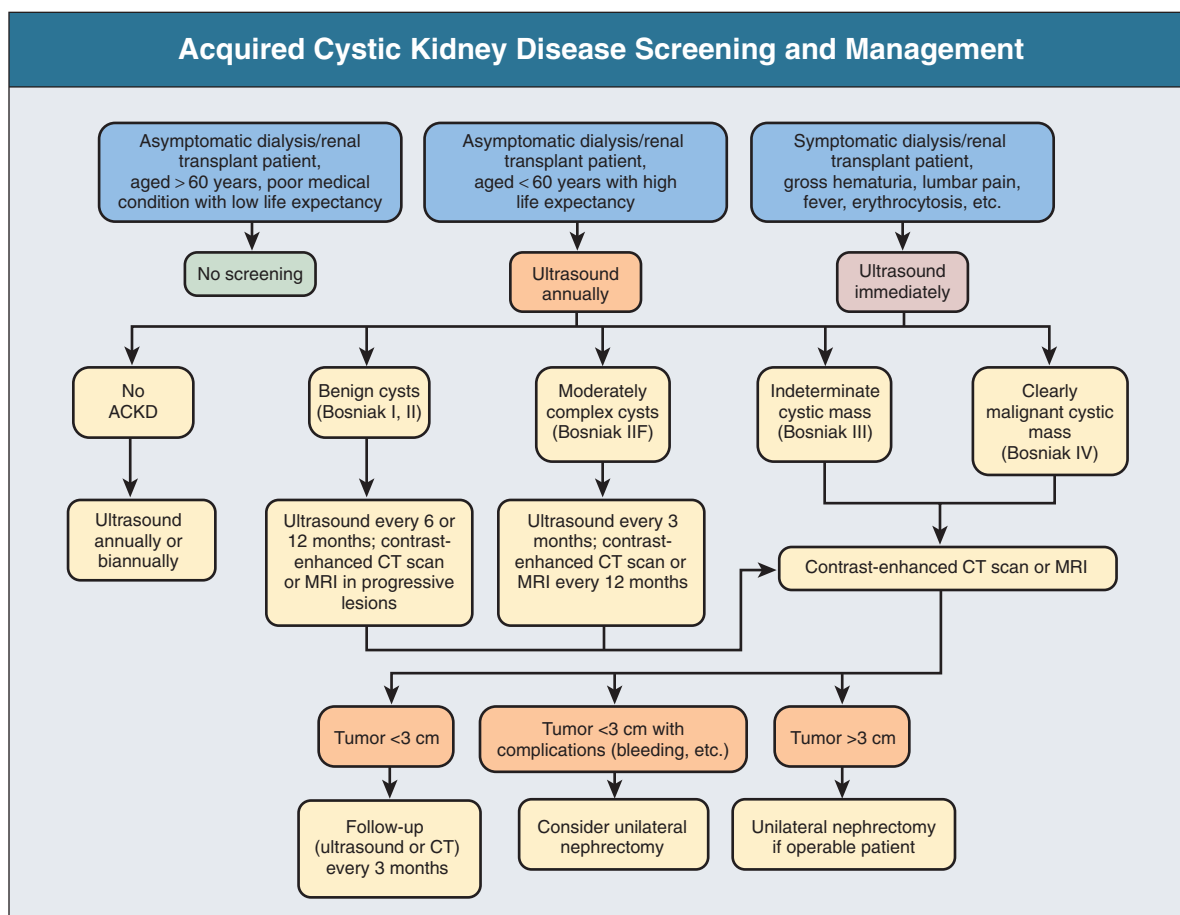

Figure 85.5 Proposed approach to acquired cystic kidney disease (ACKD) screening and management of suspected renal cell carcinoma. ACKD, acquired cystic kidney disease; CT, computed tomography; MRI, magnetic resonance imaging. (Modified from references 5, 7, and 16.)

considered for nephrectomy also in case of tumors with diameters less than 3 cm. In general, tumor enlargement should be used as an indication for nephrectomy if it is permitted by the patient's status. When complications such as back pain and persistent hematuria are present, nephrectomy has been recommended by some but not all authors.⁷

A prophylactic contralateral nephrectomy, in the case of unilateral tumors, is not routinely recommended because of the morbidity associated with the procedure, the worsening of anemia, and the loss of residual renal function in those who are not considered transplant candidates. A delay of transplantation is generally not suggested in patients who have had an asymptomatic RCC associated with ACKD in their nephrectomy. In such a setting, a contralateral nephrectomy can be recommended to decrease the potential risk of neoplastic growth and to avoid a delay of transplantation.

MALIGNANT NEOPLASMS IN DIALYSIS PATIENTS

Even if the risk of malignant transformation of ACKD is disregarded, dialysis patients have a slightly higher cancer risk compared with the general population. Analysis of more than 800,000 dialysis patients in three registries from the United States, Europe, and Australia/New Zealand revealed that most of the increased risk was due to cancers of the kidney, bladder, and endocrine organs (Fig. 85.6).¹⁷ Besides the specific risk associated

with malignant transformation of ACKD, some of the increased risk is directly related to the underlying renal disease or to the immunosuppression that may have been administered to patients with immune-mediated renal disease. Cyclophosphamide therapy, for example, may predispose to bladder and ureteral cancer that presents after patients have been initiated on dialysis. Renal disease or immunosuppressive therapy may underlie the apparent risk of dialysis patients for development of multiple myeloma (see Fig. 85.6). In addition, patients with analgesic nephropathy or Chinese herbs/aristolochic acid nephropathy are at high risk for development of transitional cell carcinoma of the upper urinary tract.¹⁸ Particularly after renal transplantation, these tumors tend to be less differentiated and in an advanced stage, and therefore the patients have a relatively poor outcome. For this reason, patients with analgesic nephropathy and aristolochic acid nephropathy should be screened for the presence of transitional cell carcinoma before transplantation and annually after transplantation. It has been advocated that screening should include cystoscopy, retrograde ureteral catheterization with washings and brushings, and sonography imaging.¹⁹ Other malignant neoplasms that have been observed at increased frequencies in dialysis patients include carcinoma of the cervix, thyroid and other endocrine neoplasias (see Fig. 85.6), and, at least in the USRDS database, a 1.5- to 2-fold increase in the risk for non-Hodgkin's lymphoma, Hodgkin's disease, and leukemias.¹⁷ This suggests that female dialysis patients should undergo gynecologic screening including cervical smear in the same intervals as suggested for the general population. Regular

Figure 85.6 Cancer risk in dialysis patients. Relative risk of cancer (plus 95% confidence interval) compared with the general populations in 831,804 dialysis patients from Australia/New Zealand (blue diamonds), Europe (orange circles), and the United States (purple circles). (Modified from reference 17.)

thyroid ultrasound is probably also justified, although no formal decision analysis is available to support this recommendation; lymphoma and leukemia screening will be difficult to impose, and clinical vigilance is advocated.

Approach to Renal Replacement Therapy

Hugh C. Rayner, Enyu Imai

TREATMENT OPTIONS FOR RENAL REPLACEMENT THERAPY

Resources available for renal replacement therapy (RRT) vary substantially between countries. If effective chronic kidney disease (CKD) management minimized progression to end-stage renal disease (ESRD) and RRT were universally available for everyone who could benefit from it and wished to have it, the incidence rates of new dialysis patients would reflect the epidemiology of irretrievably progressive kidney disease. In reality, incidence rates of ESRD treatment show huge variation, far larger than can be explained by disease incidence alone (Fig. 86.1). Clearly, there are other factors involved in the transition from CKD to RRT.

Each modality of RRT needs particular preparation, has substantial costs, and once started may continue for years. Education about RRT should be given to all patients and their families as they approach ESRD and should include the rationale, efficacy, and prognosis of each RRT modality as well as information about any relevant limitations of medical resources.

PREDICTION OF THE START OF DIALYSIS

Predicting the start of dialysis is important for preparation for RRT and is made easier if renal function is routinely measured by an estimate of the glomerular filtration rate (eGFR) derived by the Modification of Diet in Renal Disease (MDRD) formula (see Chapter 3). It is very easy to underestimate the severity of renal impairment from serum creatinine values, especially in elderly patients. Graphs of eGFR against time make it easy to identify those patients whose renal function is deteriorating at a rate that predicts they will require dialysis in the next 1 to 2 years and who therefore should be referred to the multidisciplinary team (Fig. 86.2). This is preferable to adopting an arbitrary threshold eGFR.¹

MULTIDISCIPLINARY PREDIALYSIS CARE

Multidisciplinary care should begin at CKD stage 4 (eGFR <30 ml/min per 1.73 m²). One aim of a predialysis program is to ensure that patients and their families know as much as they wish to know about renal failure and its treatment before dialysis needs to be started. To achieve this aim, sufficient time is needed to allow the large amount of information to be absorbed and its implications for that individual to be understood. This may take months rather than days in patients who have difficulty accepting information about their illness but who may gain particular

benefit from the program.² It is our practice to transfer patients to the care of a multidisciplinary team at least 12 months before the predicted date of dialysis.

Predialysis care should address a number of issues: preserving residual renal function; preventing or treating complications of CKD; ensuring that patients have sufficient understanding of their condition to decide whether they wish to have dialysis or not and to choose between PD and HD; arranging appropriate access; and in appropriate patients, preparing for kidney transplantation.

Predialysis care is best delivered by a multidisciplinary team.^{3,4} Such teams commonly include a dietitian, a nurse educator, a pharmacist, a social worker, and sometimes a trained peer-support volunteer. Patients receiving this additional care have better biochemical results, are more likely to start dialysis in a planned way with less hospitalization, and may even have improved survival rates once they have started dialysis.⁵ As well as being good practice, these programs make good financial sense as the savings in inpatient costs from such programs outweigh those required to run the clinics. Lack of access to effective predialysis care is a significant issue in the United States. Only one third of patients older than 67 years who started RRT in the United States between 1996 and 1999 had seen a nephrologist at least 4 months before starting dialysis,⁶ and this may partly explain the higher incidence rate of RRT in the United States compared with Europe.⁷

Predialysis Education Programs

Patients with advanced CKD may not gain sufficient knowledge and understanding of their condition from conventional office consultations, even when they have been seen on multiple occasions by a nephrologist. This education gap is greater among African Americans than among Asians and Caucasians.⁸

To be effective, education of the patient should follow the principles of adult learning: assess the patient's existing level of knowledge and understanding; build on this knowledge by the delivery of appropriate information in an appropriate form; and establish that the patient has understood and accepted the information given. Education can be delivered individually or in groups.⁹ In a group session, the wide range of patients' pre-existing understanding may make it difficult for the organizer to achieve the right level of detail and complexity. On the other hand, patients probably learn as much from fellow patients within a support group as they do from the group's facilitator. Furthermore, a group will help patients and their relatives appreciate that they are not alone in facing the demands of ESRD. The educational value of individual patient

Figure 86.1 Incidence of end-stage renal disease (ESRD) per million population, 2006. Data are presented only for those countries from which relevant information was available.

Figure 86.2 Predicting initiation of dialysis. Use of graph of estimated GFR (by MDRD equation) against time to schedule preparation for dialysis. Symptoms of renal failure increase as GFR falls below 20 ml/min per 1.73 m² and usually become sufficiently severe to justify dialysis below 10 ml/min per 1.73 m². The patient is referred to the predialysis multidisciplinary clinic when GFR falls below 20 ml/min per 1.73 m² or at least 12 months before the predicted need for dialysis.

consultations can be increased by the physician writing a letter to the patient summarizing the patient's medical details and the discussion about his or her treatment. This can be in addition to or in place of the conventional letter to the patient's general practitioner.

The predialysis program should be delivered by representatives of all members of the multidisciplinary team, both medical and nonmedical. For example, a controlled trial from California has studied the value of social worker input to the predialysis program in reducing unemployment.¹⁰ In the intervention group, patients and their relatives met regularly with a licensed social worker both before and after starting dialysis to explore strategies for continuing the patient's current employment. The aim of the education and counseling was to change the perception among patients, relatives, and employers that dialysis patients are unable to continue working. Blue-collar workers in the intervention group were 2.8 times more likely to continue working. Patients in work had a better quality of life, greater self-esteem, and a more positive attitude to work. As it is difficult for dialysis patients to regain jobs once they are lost, this result is particularly valuable for the long-term rehabilitation of patients.

In addition to formal sessions, patients should be made aware of the wide range of educational materials available. A number of books have been written specifically for dialysis patients. Many national organizations provide information on the Internet and produce patient information leaflets and audio-visual material, for example, the National Kidney Foundation (www.kidney.org).

Education About Transplantation

The possibility of kidney transplantation should be considered for each new patient with ESRD. For those who are suitable, transplantation offers the prospect of improved survival and quality of life. In a U.S. study, although the risk of death was 2.8 times higher in the first 2 weeks after transplantation compared

with remaining on dialysis, the long-term mortality rate was 48% to 82% lower among transplant recipients than among patients remaining on the waiting list, with relatively larger benefits among patients who were 20 to 39 years old, Caucasian patients, and younger patients with diabetes.¹¹

The options of deceased donor and live donor kidney transplants, as well as combined kidney and pancreas transplants for people with diabetes, should be discussed. Whereas outcome data from the local transplanting centers should be made available, published data can be used to inform patients.

The ideal time for the transplant to be performed is before dialysis is ever begun, so-called preemptive transplantation. A U.S. study showed that preemptive transplantation was associated with a 52% reduction in the risk of graft failure during the first year after transplantation, an 82% reduction during the second year, and an 86% reduction during subsequent years compared with transplantation after dialysis. Increasing duration of dialysis was associated with increasing odds of rejection within 6 months of transplantation, possibly due to immunologic stimulation during long-term dialysis.¹²

WHEN SHOULD DIALYSIS BE STARTED?

Patients with eGFR below 15 ml/min per 1.73 m² should be monitored regularly and dialysis started when symptoms of uremia develop. The serum levels of urea and creatinine will vary according to the patient's protein intake and muscle mass, respectively, and there is no single value of either that can be used as a threshold for starting dialysis.

The mean eGFR at the start of dialysis varies between countries and has steadily increased during recent years. The mean eGFR at start of RRT in the United Kingdom has increased from 6 ml/min per 1.73 m² in 1997 to 8.5 ml/min per 1.73 m² in 2006 (www.renalreg.com, U.K. Renal Registry 2007 Report), which compares with 11 ml/min per 1.73 m² in the same year in the United States (www.USRDS.org, 2008 Report).

A higher threshold may be used in diabetics, as they tend to tolerate uremia poorly and are frequently troubled by sodium retention and fluid overload. Other measurements to be taken into consideration include rising serum phosphate, falling serum bicarbonate, and protein-energy malnutrition, which develops and persists despite vigorous attempts to optimize intake. A fall in serum albumin is a late sign of reduced protein intake and debility. National Kidney Foundation Disease Outcomes Quality Initiative guidelines for initiation of dialysis are shown in Figure 86.3.

Arbitrary guidelines have been established to gain Medicare approval for dialysis reimbursement in the United States. These include eGFR below 15 ml/min per 1.73 m² for patients older than 18 years and below 20 ml/min per 1.73 m² (Schwartz formula) for those younger than 18 years. Alternatively, adults should have a serum creatinine concentration of more than 8 mg/dl (700 μmol/l; >6 mg/dl [530 μmol/l] in diabetes). Patients may also qualify for Medicare if they do not meet these criteria but have uremic symptoms (nausea, vomiting, pericardial pain, acidosis, or hyperkalemia) or pulmonary edema refractory to diuretics.

Limitations of a Purely Clinical Approach to the Initiation of Dialysis

Waiting for patients to develop uremic symptoms, such as anorexia, nausea, vomiting, and loss of lean body weight, carries the risk that the patient will start dialysis in a malnourished state

When to Initiate Dialysis

Indications for early start on dialysis

- Intractable fluid overload
- Intractable hyperkalemia
- Malnutrition due to uremia
- Uremic neurologic dysfunction
- Uremic serositis
- Functional deterioration otherwise unexplained

Uremic cognitive dysfunction can affect learning

Therefore, home-based self-dialysis may need to start earlier than center-assisted dialysis.

Start of dialysis may be delayed if patient is

asymptomatic, awaiting imminent kidney transplant, awaiting imminent placement of permanent HD or PD access, or, after appropriate education, has chosen conservative therapy.

If start of dialysis is delayed,

patient should be re-evaluated regularly to see if dialysis has become necessary.

Patients who choose PD

should not be required to have HD access placed, but venous sites for possible future HD access in arms should be preserved since HD may be required in the future. Incremental start on PD may be considered if there is significant residual renal function.

Nephrologists should consider conservative (nondialysis) treatment of kidney failure an integral part of their clinical practice.

Figure 86.3 When to initiate dialysis. HD, hemodialysis; PD, peritoneal dialysis. (Modified from NKF KDOQI Clinical Practice Guideline for initiation of dialysis. http://www.kidney.org/professionals/Kdoqi/guideline_upHD_PD_VA/pd_rec1.htm.)

with an increased risk of mortality. Renal failure itself is a catabolic state, and it is commonly difficult for patients on dialysis to regain lost weight.

Given the chronic nature of renal disease, patients frequently remain unaware of the severity of their illness. Protein intake may fall spontaneously with the result that symptoms of uremia do not develop, but this is at the expense of a loss of lean body mass. Similarly, patients may gradually reduce their activities as their exercise tolerance declines. It is only when dialysis is started that many patients appreciate how ill they have become.

Lack of awareness is a trap that can be avoided by carefully questioning the patient for insidious symptoms of uremia. For example, the patient should be asked to compare his or her current eating habits and lifestyle with those 6 to 12 months previously. Close friends and relatives provide a useful third-party view of the patient's well-being.

Limitations of a Purely "Laboratory Result–Based" Approach to the Initiation of Dialysis

Routine early initiation of dialysis would need to confer significant benefits to justify the added inconvenience to the patient, the additional risk of dialysis-related complications, and the additional cost. As dialysis treatment has a finite life, from loss of peritoneal function or failure of hemodialysis (HD) access, starting treatment earlier will bring forward the time when more procedures or a change of modality is necessary.

Moreover, there is likely to be resistance from many patients to the suggestion that they should start dialysis when they have

no symptoms of uremia. The nephrologist would need complete confidence in the laboratory values as well as in the evidence supporting early commencement of dialysis to persuade a reluctant, asymptomatic patient.

Starting dialysis is the first step in a lifelong commitment to RRT. Patients will be asked to comply with a wide variety of inconvenient and sometimes unpleasant treatments. A high level of compliance is required for a successful outcome, and particularly in the United States, there is concern about the level of noncompliance, which is associated with increased mortality.¹³ It seems reasonable to presume that the commitment to dialysis is likely to be greater if the patient feels better after it has started.

A prospective study in Holland provides useful data to help the patient and nephrologist agree when to commence treatment.¹⁴ Those patients who started dialysis with less residual renal function (5 ml/min per 1.73 m² versus 7 ml/min per 1.73 m²) had a poorer quality of life in the early period after starting dialysis. However, this difference was no longer present by the end of the first 12 months of treatment. The study was too small to demonstrate a difference in mortality.

Starting dialysis earlier will lead to an apparent increase in survival if survival is measured from the time dialysis begins, so-called lead-time bias. A randomized controlled trial of early (GFR 10–14 ml/min) or late (GFR 5–7 ml/min) or when symptoms supervened initiation of HD showed no difference in mortality or other clinical outcomes.¹⁵

THE CHOICE BETWEEN PERITONEAL DIALYSIS AND HEMODIALYSIS

The majority of patients with ESRD are suitable for treatment with either peritoneal dialysis (PD) or HD. It is difficult to envisage an ethically acceptable trial in which patients are allocated randomly to PD or HD, and the various possible modifications within each modality make a simple comparative trial impractical. Retrospective comparative studies have failed to indicate a consistent survival advantage for either modality.^{16,17} A prospective cohort study from 81 U.S. dialysis clinics attempted to overcome the limitations of these studies, although it was still not a randomized study.¹⁸ No significant difference in outcomes was found between HD and PD during the first year of treatment; but in the second year, the risk of death was significantly greater in those on PD. The increased risk was mainly in patients with cardiovascular comorbidity and is consistent with two other U.S. studies that showed patients with coronary artery disease and congestive heart failure have a shorter survival on PD than on HD. This contradicts a commonly expressed opinion that PD is more “gentle” for such patients as it avoids rapid fluid shifts and causes less “stress” on the heart.^{19,20}

When making their choice, patients should be aware that the chances of a change in treatment modality may be up to fivefold greater for PD (to HD) than for HD (to PD) and that change in treatment from PD to HD is associated with an increased risk of hospitalization and mortality.²¹ A planned change from PD to HD may not be associated with this increased risk, although this has not been studied systematically in a large population.

Contraindications to Peritoneal Dialysis

There are a few situations in which PD is contraindicated (Fig. 86.4). These have been agreed to by the consensus panel of the

Contraindications to Dialysis Modalities	
Peritoneal Dialysis	
Absolute	Relative
Loss of peritoneal function	Recent abdominal aortic graft
Producing inadequate clearance	Ventriculoperitoneal shunt
Adhesions blocking dialysate flow	Intolerance of intra-abdominal fluid
Surgically uncorrectable abdominal hernia	Large muscle mass
Abdominal wall stoma	Morbid obesity
Diaphragmatic fluid leak	Severe malnutrition
Inability to perform exchanges in absence of suitable assistant	Skin infection
	Bowel disease
Hemodialysis	
Absolute	Relative
No vascular access possible	Difficult vascular access
	Needle phobia
	Cardiac failure
	Coagulopathy

Figure 86.4 Contraindications to dialysis. Absolute and relative contraindications to hemodialysis and peritoneal dialysis. (Modified with permission from reference 22.)

National Kidney Foundation Dialysis Outcomes Quality Initiative.²² Relative contraindications to PD include the following.

Fresh Intra-abdominal Foreign Body

Patients with prosthetic aortic grafts have been successfully treated with PD. HD is usually used initially for up to 16 weeks to allow the graft to be covered with epithelium and so avoid the risk of graft infection through peritoneal dialysate. However, this risk must be balanced against that of bacterial seeding from the patient's HD access.

Body Size Limitations and Intolerance of Intra-abdominal Fluid Volume

Body size can be a problem at both ends of the spectrum. Small patients may be intolerant of the volume of dialysate needed to achieve adequate dialysis, particularly if they have negligible residual renal function. Alternative methods of fluid exchange, such as nocturnal automated PD, can be used to overcome this limitation. It may also be difficult to achieve adequate clearances in patients with a body mass index above 35 kg/m². Discomfort due to increased intra-abdominal volume can be significant in patients with chronic respiratory disease, low back pain, or large polycystic kidneys. In general, it is difficult to predict a patient's tolerance of intra-abdominal fluid, and so these limitations usually appear after a patient has started PD.

Bowel Disease and Other Sources of Infection

The presence of ischemic bowel disease, inflammatory bowel disease, or diverticulitis is likely to increase the incidence of peritonitis due to organisms passing through the bowel wall into the peritoneum. Abdominal wall infection may lead to peritonitis through the exit site and catheter tunnel.

Screening for methicillin-resistant *Staphylococcus aureus* (MRSA) before all elective surgical procedures is National Health Service policy in the United Kingdom. Nasal carriage of *S. aureus* increases the risk of subsequent staphylococcal exit site infection and peritonitis, and clearance of nasal *S. aureus* with topical mupirocin cream has been shown to reduce significantly the risk of staphylococcal infection at the exit site.²³

Severe Malnutrition or Morbid Obesity

Patients should ideally commence PD in an adequate nutritional state. Severe malnutrition may lead to poor wound healing and to leakage from the catheter tunnel. In addition, peritoneal protein losses during dialysis may exacerbate hypoalbuminemia and be particularly severe with continuous ambulatory PD (CAPD) peritonitis. At the other end of the spectrum, it may prove difficult to place a peritoneal catheter satisfactorily through the abdominal wall in patients with morbid obesity. Thereafter, absorption of glucose from the dialysate, which may average as much as 800 calories per day, may contribute to further weight gain.

Contraindications to Hemodialysis

Contraindications to HD are few (see Fig. 86.4). As discussed in Chapter 87, access to the circulation can usually be obtained, even in patients with extensive vascular disease or previous surgery. An aversion to needle puncture of the arteriovenous (AV) fistula is common in the early stages but can usually be overcome by careful use of local anesthetic and nursing encouragement. Severe coagulopathy may make management of anticoagulation for the extracorporeal circuit difficult.

HOME HEMODIALYSIS

In the last two decades, the use of home HD has declined. For example, in the United Kingdom, the percentage of the dialysis population on home HD fell from 35% in 1984 to 2% in 2006.

France, Australia, and New Zealand are the only countries with a significant proportion of patients on home HD (Fig. 86.5). This has occurred for a variety of reasons. First, HD usually requires the presence of an assistant throughout the period of dialysis in case the patient becomes hypotensive or unconscious. As an increasing proportion of new dialysis patients are elderly, there may be no one available who is able or willing to take on this considerable responsibility. Second, there is the added cost of installing a dialysis machine and its associated water treatment, which is not required for PD. However, the subsequent running costs are less for home than in-center HD.

Home HD can provide significant benefits for appropriate patients. It removes the inconvenience of traveling to and from the dialysis facility and gives patients the freedom to dialyze at a time to suit themselves. As a result, they are able to perform more hours of treatment per week with less disruption to their lives. Although there is no randomized, controlled trial comparing hospital and home HD, comparative studies, in which correction has been made for differences in comorbidity, do suggest that patients on home HD have a better outcome in terms of morbidity and mortality.²⁴ Selected patients are able to dialyze every night at home. This gives much greater clearance than is possible with thrice-weekly dialysis, and major improvements in anemia, blood pressure, and phosphate control have been demonstrated. The inconvenience of nightly treatment is balanced by the removal of dietary restrictions and antihypertensive medications and an improved quality of life.²⁵ In 2002, the U.K. National Institute for Health and Clinical Excellence recommended that “all patients who are suitable . . . should be offered the option of

Figure 86.5 Prevalent distribution of dialysis patients by modality, 2006. Data are presented only for those countries from which relevant information was available. All rates are unadjusted. CAPD, continuous ambulatory PD; CCPD, continuous cycling PD; HD, hemodialysis.

having HD in the home” (www.nice.org.uk/Guidance/TA48), and with improvements in dialysis machine technology, this form of treatment is becoming more widespread.

PATIENT'S CHOICE OF HEMODIALYSIS OR PERITONEAL DIALYSIS

In the facility of one of the authors (HCR) in Birmingham, U.K., all patients entering the ESRD program are given “modality-neutral” counseling and allowed to select their preferred mode of treatment.²⁶ Between 1992 and 1998, the patient's choice was restricted for medical reasons by the physician in 54 of 333 patients (16%), PD being contraindicated in 51 of the 54. Of the remainder, 55% chose HD and 45% PD. These relative proportions are the same as those found in a study of 5466 U.S. patients who received a program of predialysis education.²⁷ Independent predictors for choosing HD in our study were increasing age and male sex. Independent predictors for choosing CAPD in the United Kingdom and the United States include being married, being counseled before the start of dialysis, and increasing distance from home to the base unit.²⁸

Of those able to choose, almost all patients can be started on their preferred modality of dialysis.²⁴ However, in the United States, whereas 45% of patients chose PD, only 33% actually started dialysis on this modality.²⁷ Furthermore, the major differences in dialysis modality between countries (see Fig. 86.5) suggest that the type of dialysis is more often decided by physicians rather than by patients. Possible factors affecting these decisions are discussed next.^{29,30}

Arrangements for the Reimbursement of Physicians and Funding of Dialysis Facilities

The arrangements by which physicians and dialysis facilities are reimbursed for the cost of providing treatment vary widely around the world. There are also large differences between the levels of payment for HD and PD in many countries. For example, in French clinics, the facility is not reimbursed for PD and the physicians receive no fee. In countries such as the United Kingdom and Canada, where facilities are publicly funded from taxation, the use of more expensive types of HD (e.g., high-flux hemodiafiltration) is limited. Conversely, in places such as Hong Kong, where dialysis is available only in the private sector, more patients are treated by PD than by HD, as PD is less expensive. In HD facilities, an arrangement whereby payment depends on the number of patients treated creates pressure to increase patient numbers. If the patient's nephrologist has a financial interest in the HD facility, this may directly influence the decision on which modality of treatment to recommend.

Physician Preference

In a USRDS survey reported in 1997, only 25% of HD patients remembered having PD discussed with them. In contrast, 68% of patients on PD reported discussions about HD. Interestingly, a much greater proportion of patients on HD thought that the choice had been made by the medical team rather than by either themselves or by joint decision. There has been a marked decline in the proportion of dialysis patients treated by CAPD in the United States, from 14% in 1995 to 8% in 2006. This compares with 20% in the United Kingdom in 2006. In Japan, approximately 50% of ESRD patients will survive on dialysis for more

than 10 years; the physician therefore needs to consider the suitability of a dialysis modality for 10 years or more of treatment. Most Japanese physicians prefer HD because of better long-term outcome; alternatively, they start with PD and change to HD after 5 to 7 years of treatment.

THE IMPORTANCE OF DIALYSIS ACCESS

Ideally, every patient would make an informed choice between PD and HD after a period of in-depth counseling and preparation, and dialysis access would be established in advance of starting dialysis. Sadly, dialysis is frequently started in less than ideal circumstances. Late presentation is a worldwide phenomenon, indicating that no system of health care has overcome the problems of identifying patients with CKD and bringing them to the attention of nephrologists in time (Fig. 86.6).^{31,32}

Reports from both Europe and the United States document the excess morbidity and mortality for patients presenting late in ESRD and requiring dialysis as an emergency procedure.³³ Patients starting dialysis as an emergency usually receive HD through a catheter and tend to remain on HD rather than converting to PD. Compared with nonemergency patients, their length of hospital stay is significantly greater, and during this time, there is a higher incidence of major complications and death. A significant part of the increased mortality is related to the use of a catheter rather than a permanent AV fistula. In the United States, many incident patients receive an AV graft rather than a fistula as it is believed that grafts can be cannulated more easily and earlier than fistulas (Fig. 86.7).³⁴

International data from the Dialysis Outcomes and Practice Patterns Study showed a 37% increase in the relative risk of death in patients dialyzing through a catheter and a 19% increase in patients using a graft compared with a native AV fistula, after adjustment for a wider range of demographic and comorbid factors.³⁴ The detrimental effects of central venous catheters persist even after the catheter has been removed. The survival rate of subsequent AV fistulas is significantly worse in patients who have had a previous catheter in place compared with those who started directly on a fistula, even after correction for case-mix and comorbidity, possibly because of development of central venous stenosis after the catheter has been removed.³¹ There is wide variation in countries in the time required for permanent access to be created and used.³¹ If a fistula can be created swiftly and used as soon as it is mature, perhaps after only 2 weeks, the need for a catheter may be avoided. Details of HD access surgery are discussed in Chapter 87, and PD catheter placement is discussed in Chapters 88 and 92.

THE DECISION NOT TO OFFER RENAL REPLACEMENT THERAPY

The Availability of Dialysis Facilities

RRT is unavailable to the majority of the world's population with renal failure.³⁵ A strong relationship exists between the number of patients on RRT per million population and a country's per capita income: 644 in the 15 European Union countries (average gross per capita income, >U.S. \$22,000) compared with 166 in central and eastern European countries (average income, U.S. \$4,480) and 52 in Bangladesh (average income, U.S. \$370). The practice of rationing dialysis has been candidly documented in a report from a South African center³⁶ in which more than half the patients with ESRD assessed between 1988 and 2003 were not

Figure 86.6 Variations in predialysis care. Percentage of patients starting hemodialysis having seen a nephrologist more than 1 month or 4 months previously by country. (Data from the *Dialysis Outcomes and Practice Patterns Study*. www.dopps.org.)

offered dialysis; socioeconomic factors such as age, race, employment, and marital status outweighed medical factors in the decision to begin treatment.

Selection of Patients by Physicians and Nephrologists

Incidence rates of RRT have steadily increased during recent decades. Some but not all of this is due to the increasing prevalence of ESRD. A long-term study from California has shown a steady increase in the likelihood of going on to receive RRT without there being an increase in risk factors for ESRD, such as age, diabetes, high blood pressure, proteinuria, and reduced eGFR, or a fall in premature deaths from other causes.³⁷ This indicates a greater enthusiasm to start RRT in recent years.

In the developed world, the practice of starting dialysis in patients who are very elderly or dependent on others for their care or who have multiple comorbid conditions varies significantly between countries and between nephrologists within those countries.^{38,39} For example, the percentage of patients who were living in a nursing home or who were unable to eat independently within 90 days of starting dialysis is much higher in the United States (11.6%) and Japan (19.2%) than in France (1.3%), Germany (6.4%), Italy (4.7%), Spain (2.0%), and the United Kingdom (1.5%).³⁸ The average age at start of dialysis in Japan is 66.8 years. In 2008, 6065 patients in Japan were older than 80 years at the initiation of dialysis, and 422 patients were older than 90 years.⁴⁰ The odds of new patients being older than 80 years

Figure 86.7 Country differences in vascular access use at start of hemodialysis. Percentage of patients starting hemodialysis with an arteriovenous fistula, an arteriovenous graft, or an intravenous catheter, by country. (Data from the *Dialysis Outcomes and Practice Patterns Study*. www.dopps.org.)

are significantly lower in units whose medical directors agree that they do not start dialysis in the very elderly.³⁸

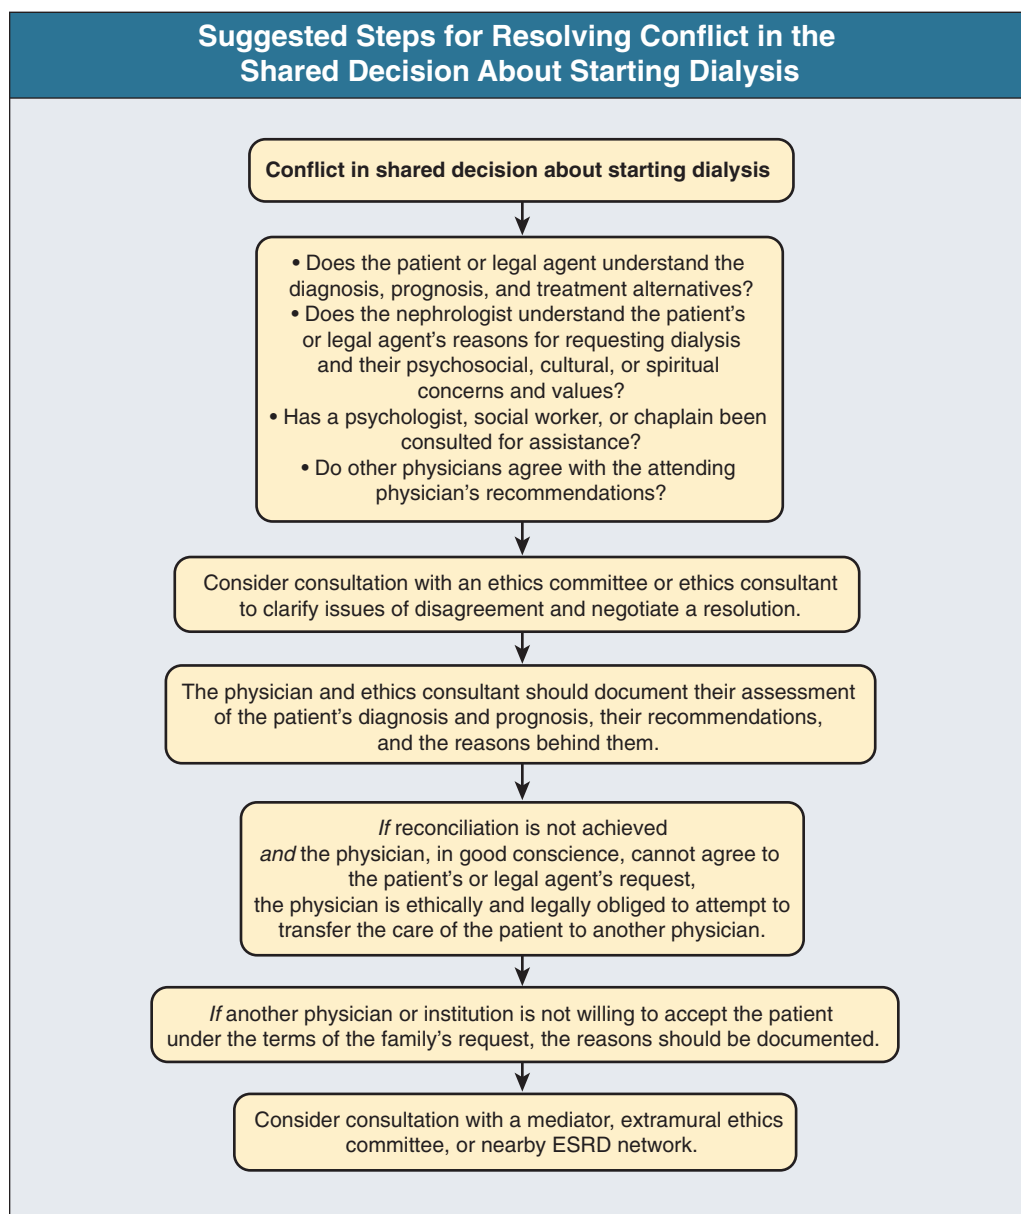

Severe intellectual impairment in a patient would much more strongly influence a nephrologist in the United Kingdom not to start dialysis than in the United States.^{38,39} Furthermore, nephrologists in the United States were much more likely than those in the United Kingdom and Canada to start dialysis in patients with dementia or in a persistent vegetative state, if pressured to do so by family members. In a recent report from the Japanese Society for Dialysis Therapy, 1326 of 15,239 new dialysis patients (8.7%) had some intellectual impairment.⁴⁰ Fear of litigation was particularly influential in persuading Japanese, U.S., and Canadian nephrologists to offer treatment.³⁹

The Renal Physicians Association and American Society of Nephrology (RPA/ASN) guidelines for the initiation of dialysis in the United States provide a systematic approach to conflict resolution if there is disagreement about the benefits of dialysis (Fig. 86.8).⁴¹

RATIONING OF DIALYSIS TREATMENT

On the grounds that the greatest good should be derived from the limited resources available, it has been argued that patients who are expected to survive for only a few months should not be offered dialysis. This is supported by the view that it is preferable to avoid suffering by not starting dialysis than to withdraw treatment when

Figure 86.8 Suggested steps for resolving conflict in the shared decision about starting dialysis. (Modified from reference 41.)

the patient's condition becomes distressing.⁴² Withdrawal of dialysis seems more like actively causing death than withholding of dialysis, where death is allowed to occur "naturally."

This utilitarian approach to the allocation of resources is contrary to the instincts of most physicians to act in the patient's best interest and may be unacceptable to many physicians. Furthermore, it does not take into account the value of even a short extension of life that allows the patient and his or her family to prepare for death. It also makes only a small contribution to minimizing the use of resources as the costs of a HD program are in proportion to the length of time that the patient continues to receive treatment.

Against this ethical background, are there any objective criteria that can be applied to identify patients who are unsuitable for dialysis? One criterion to be dismissed is age. Although advanced age was used as a simple exclusion criterion in the early days of dialysis, the elderly are now the most rapidly growing section of the dialysis population.

Predictive Factors

Two studies have attempted to identify other predictive factors. In a prospective Canadian study of patients starting dialysis,⁴³ a comorbidity scoring system was used to quantify factors likely to predict early death. The predictive value of this scoring system was compared with the value of an estimate made by the patient's nephrologist of the probability that the patient would die within 6 months. It was not possible to predict early death accurately by either the comorbidity scoring system or the clinician's opinion. Indeed, it was impossible even to identify the small proportion of patients with a very poor prognosis. Clinicians were more accurate than the scoring system in identifying patients with less than a 50% risk of death by 6 months, but they tended to overestimate the risk of death in the worst prognostic groups. For example, 30% of patients whose predicted probability of death was considered to be 80% or higher survived for more than 6 months.

In a U.K. study,⁴⁴ a high-risk group of 26 patients was identified by factors associated with poor survival in a statistical model,

which included poor functional status at presentation, comorbidity, and underlying disease. Although these patients had a 1-year survival of only 19.2%, four patients survived at least 2 years. Furthermore, the cost incurred by this high-risk group was only 3.2% of the total cost of the chronic dialysis program.

ADVISING PATIENTS ABOUT PROGNOSIS ON DIALYSIS

Despite these uncertainties, an individual patient should be given an estimate of his or her likely future on dialysis. Factors associated with a poorer prognosis in a large number of studies include advanced age, male gender, decreased serum albumin, malnutrition, impaired functional status, diabetes mellitus, and coronary heart disease. Quality of life is strongly predictive of mortality, even after statistical correction for these comorbid factors.⁴⁵

For patients whose prognosis is particularly uncertain, or when there is disagreement between the views of the patient and the dialysis team, a time-limited trial of dialysis may be offered.⁴¹ This will give the patient and his or her family a better understanding of what life on dialysis entails and allow time for further discussion between all parties. The duration of the trial should be judged for each individual and clinical and biochemical parameters reviewed regularly. In our experience of 31 patients older than 79 years on HD, 10 patients who were hypoalbuminemic at the start of dialysis and whose serum albumin had fallen by more than 3 g/l to 30 g/l or less after 4 weeks on dialysis had all died by 6 months. The median survival of the other 21 patients was 1.3 years.

Most people would agree that patients who are certain to have an unacceptable quality of life should not be subjected to the discomfort of dialysis. Elderly patients with multiple comorbidities, particularly ischemic heart disease, have been shown to have survival rates with conservative therapy without dialysis that are equivalent to those of patients receiving dialysis.⁴⁶ Sparing such patients the inconvenience and discomfort of hospital attendances, surgical access procedures, and dialysis treatments is a major benefit.

Many of the symptoms and complications of ESRD (e.g., anemia, acidosis, pruritus, insomnia, depression, fluid overload, and hypertension) can be treated with medication and low-protein diet,⁴⁷ and so a decision not to start dialysis is not the same as a decision to withhold active treatment. Such “conservative” therapy is best delivered by the specialist multidisciplinary team that delivers care to all patients with ESRD not yet on dialysis, which should include a dietitian, social worker, and psychological support. The team should have close links with palliative care specialists so that there is a smooth transition from active medical therapy to terminal care.

THE PATIENT WHO DOES NOT WANT DIALYSIS

Nephrologists may be presented with the dilemma of a mentally competent patient whom they would normally treat but who does not wish to have dialysis.⁴¹ From an ethical viewpoint, decisions not to start dialysis and to withdraw dialysis are justified on the principle of individual autonomy. Legally, they are based on the individual's common-law right to self-determination in the United Kingdom and on the constitutional right of liberty in the United States. Where the patient is able to express a clear wish, the physician is obliged to respect this because to treat a patient against his or her will would constitute an assault. The physician

must nonetheless ensure that all reversible factors have been addressed, such as unfounded fears about what dialysis will entail or a depressive illness affecting the patient's judgment, and ideally request a psychiatric evaluation. It is not uncommon for patients to express a strong desire not to have dialysis, particularly if they are relatively asymptomatic, only to change their mind when they become more symptomatic. At this late stage, the basic “will to survive” comes to the fore. An advance directive written by the patient should never be held as a reason against a change of mind.

DISAGREEMENT ABOUT A DECISION TO DIALYZE A PATIENT

There will inevitably be differences of opinion about the benefits of dialysis for individual patients. Dialysis nurses may disagree with the nephrologist's decision to treat a patient. If the dialysis nurses and physicians are functioning well as a team, they should be able to express these reservations and have the issue adequately discussed. It is very demoralizing for individual staff and the team as a whole if they feel pressured into giving treatment that they think is inappropriate.

The nephrologist may remain unwilling to offer dialysis despite the insistence of either the patient or, more often, the patient's care providers, the legal agent, or another physician (see Fig. 86.8). Dialysis must never be given at the insistence of others if it is against the patient's clearly expressed wishes. However, if the patient insists on treatment against the nephrologist's advice, dialysis should usually be given while a resolution is reached. Extensive discussions and explanations of the treatment options and prognosis may be needed to gain a better understanding of the reasons behind the differing views. Helpful advice may be obtained from another physician, particularly the patient's family physician, who will have a broader understanding of the patient's circumstances. It may be appropriate to involve a psychologist, social worker, or religious counselor. If the conflict persists, it may be necessary to refer the case to a formal ethics committee, if one exists locally, to clarify the issues of disagreement and to enable a resolution. A physician cannot be compelled to offer treatment against his or her considered professional judgment, but the physician is ethically and legally obliged to attempt to transfer the care of the patient to another physician. Only as a last resort, if no alternative dialysis unit can be found and after adequate advance notice has been given, should dialysis be withdrawn.⁴¹

MANAGEMENT OF DISRUPTIVE PATIENTS ON DIALYSIS

Most nephrologists have had experience of treating a small number of patients who, for one reason or another, will not comply with the discipline required for maintenance dialysis and who become disruptive to the staff and other patients. This behavior can range from noncompliance with treatment, which harms the patient but is merely inconvenient to the staff, to verbal or even physical aggression toward the staff and other patients in the unit. The impact of this small number of patients can be very great.

The strategy for dealing with such patients must be tailored to the individual. However, useful suggestions for resolving conflict have been provided in the RPA/ASN Clinical Practice Guideline⁴¹ (Fig. 86.9); they are available at www.esrdnetworks.org/networks/net6/policies/po-recom.html and have been reviewed

Suggested Steps for Dealing with Disruptive Patients

Identify and document problem behaviors and discuss them with the patient.
Seek to understand the patient's perspective.
Identify the patient's goals for treatment.
Share control and responsibility for treatment with the patient: Educate the patient so that he or she can make informed decisions. Involve the patient in the treatment as much as possible. Negotiate a behavioral contract with the patient.
Consult a psychiatrist, psychologist, or social worker for assistance in patient management or determination of decision-making capacity.
Be patient and persistent; try not to be adversarial.
Allow the patient to air concerns but do not tolerate verbal abuse or threats to staff or patients (see www.nhs.uk/zerotolerance/intro.htm).
Contact law enforcement officials if physical abuse is threatened or occurs.
If satisfactory resolution has not occurred with the above strategies, contact the local end-stage renal disease network to discuss the situation and ensure due process.
Consider transferring the patient to another facility or discharging the patient.
Consult with legal counsel before proceeding with plans for discharge and do not discharge without advance notice and a full explanation of future treatment options.

Figure 86.9 Suggested steps for dealing with disruptive patients. (Modified from reference 41.)

recently.⁴⁸ They emphasize the importance of understanding, information, patience, and persistence. However, the bottom line for patients who are aggressive toward staff while on dialysis must be that they are taken off treatment and sent home.

RESUSCITATION AND WITHDRAWAL OF DIALYSIS

Cardiopulmonary Resuscitation

If patients are to be fully involved in decision-making about their treatment, two sensitive issues need to be discussed: cardiopulmonary resuscitation (CPR) and the possibility of withdrawal of dialysis.⁴⁹ The two are not necessarily linked; patients may wish to continue with dialysis but express a desire that resuscitation not be attempted should they suffer a cardiac arrest. Such a decision would be supported by evidence on the outcome of CPR in dialysis patients: only 6 of 74 dialysis patients who received CPR survived to hospital discharge, and at 6 months after CPR, only two were still alive, significantly less than 23 of 247 “control” patients not on dialysis still alive at 6 months; this difference was not explained by age or comorbid conditions.⁵⁰ Successful CPR often resulted in a “poor-quality” death, 20 of the 27 successfully resuscitated dialysis patients dying a few days later on mechanical ventilation in an intensive care unit.

A decision not to attempt CPR must be carefully documented in the patient's medical and nursing records, and all nursing staff must be made aware of it. It is important to be clear about what is meant by “cardiac arrest” and for there to be agreement on how the nursing staff are to respond should the patient suffer a hypotensive “crash” while on dialysis. These notes may form part of a complete advance directive, as discussed next.

Withdrawal of Dialysis

As discussed earlier, it is not possible to predict accurately which patients will gain prolonged benefit from dialysis. Many nephrologists therefore maintain a liberal policy of offering dialysis to all patients with ESRD who wish to have it. This policy ensures that no patients are denied dialysis but has the inevitable consequence that a number of patients will be started on dialysis who subsequently do not enjoy an acceptable quality of life. The possibility of withdrawing dialysis needs to be addressed if these patients are not to suffer unreasonably.

Rates of withdrawal vary widely between countries and cultures. Withdrawal rates in Italy and France are much lower than in the United Kingdom and the United States.⁴⁹ In the United States, African Americans have about one-third the withdrawal rate of Caucasians. Rates of withdrawal vary between dialysis units and are significantly associated with the medical director's opinion about whether withdrawal is allowed or facilitated in that unit.³⁸ This suggests that patients' wishes are not always fully included in these decisions. Patients may be very reticent to express a wish to withdraw from dialysis. Many see it as their duty as a patient to go along with the treatment recommended by the physician and do not wish to appear ungrateful for the efforts that are being made to keep them alive. The physician may be the last member of the team to learn about the patient's views, and it is very important that good communication exist within the multidisciplinary team so that any clues that the patient gives are passed on and acted on.

Staff should adopt a proactive approach and raise the issue of withdrawal of dialysis with patients who are not thriving. There is good evidence that early discussion of these issues can lead to a more satisfactory outcome for patients, relatives, and staff when the patient eventually dies.⁵¹ In the United States, formal advance directives play an important part in these discussions, and helpful guidance on how to conduct sensitive interviews has been published.⁵² In the United Kingdom, there has been less enthusiasm for formalizing this process. This may stem from a fear that raising the subject of death with patients may destroy their hope for the future. Qualitative research suggests that the opposite may be the case.⁵³ Advance directives do not obviate the need for staff to continue to communicate closely with the patient and his or her family in case the decision changes as death comes closer.

When a patient is no longer competent to make a decision, an advance directive can provide a clear legal basis for the decision to stop dialysis. Indeed, in the absence of clear and convincing written evidence, some American states (e.g., Missouri, New York) insist that dialysis must be continued. In other American states and the United Kingdom, the physician is given the task of deciding on the patient's behalf. Helpful advice for dialysis staff and patients wishing to complete an advance directive is available in the RPA/ASN Clinical Practice Guideline⁴¹ and at the website www.ageingwithdignity.org.

Once a patient has expressed a wish for dialysis to be withdrawn or the issue has been raised by his or her relatives, the first priority must be to identify any reversible factors that may improve the patient's health sufficiently for the decision to be reversed. In particular, any depression must be identified and treated.⁵⁴ Once all these factors have been ruled out, the process of withdrawing dialysis should be managed according to some key principles (Fig. 86.10).

Withdrawal of dialysis should be seen not as an admission of failure but as a final stage in the process of RRT. The

Principles Underlying Withdrawal of Dialysis

The ultimate responsibility for the decision rests with the physician, not the relative.
The patient's interests and dignity should be protected at all times.
The process should not be rushed. If there is any doubt about the correctness of the decision, treatment should continue.
There should be an open discussion among the multidisciplinary team to avoid any damaging disagreements.
The psychological needs of the health care team should not be overlooked.
Palliative care must be given in the most appropriate environment, e.g., a hospice or, ideally, the patient's own home.

Figure 86.10 Key principles underlying the process of withdrawal of dialysis.

opportunity for patients to complete unfinished emotional and financial business can make the subsequent bereavement period much less traumatic. Managing this terminal phase can be uniquely rewarding, particularly if it allows a patient and his or her family and care givers to prepare themselves for the patient's death.⁵⁵

Vascular Access for Dialytic Therapies

Jan H. M. Tordoir

Functional vascular access is needed for all extracorporeal dialytic therapies and remains the lifeline for patients with end-stage renal disease who need chronic intermittent hemodialysis (HD) therapy. The ideal HD access should have a long length of a suitable superficial vein for cannulation in two places more than 5 cm apart with a sufficient blood flow for effective dialysis, usually in excess of 400 ml/min. A vascular access should have good primary patency, have a low risk of complications and side effects, and leave opportunities for further procedures in the event of failure. Ideally, a first access should be an arteriovenous (AV) fistula placed peripherally at the wrist. However, upper arm and lower limb access sites are increasingly used because the aging dialysis population, with multiple comorbidities, has poor and diseased arm vessels that may be unsuitable for the creation of a simple wrist fistula.

Vascular access should be performed with minimal delay by a surgeon experienced in vascular access creation and, wherever possible, in advance so that dialysis may start with permanent access rather than with use of a central venous catheter. Central venous catheter use should be minimized because of the increased risk of sepsis, the increased mortality, and the development of central venous stenosis or thrombosis, which compromises further access in the upper limbs. Unfortunately, many patients require a central venous catheter either to start dialysis or as a bridge between the failure of a permanent access and the creation of a new AV fistula.¹

The need for revisional procedures because of access-related complications, including thrombosis, central venous obstruction, and ischemia, is increasing. A multidisciplinary approach to access creation and maintenance, involving nephrologists, interventional radiologists, access surgeons, and dialysis nurses, is mandatory to meet the burden of HD vascular access on health care facilities and costs.

EVALUATION OF THE PATIENT FOR VASCULAR ACCESS

The earlier a patient with chronic kidney disease (CKD) is seen by a vascular access surgeon, the better the chance for the patient to have a well-functioning access at the initiation of HD. An early decision on the type, side, and site of the first vascular access will be based on the following:

- **Clinical examination** with careful palpation of arterial pulses and venous vasculature. Particular attention is paid to the venous filling capacity, with use of a blood pressure cuff and variable pressures, and to the presence of venous

collaterals and swelling. The dominant arm is not necessarily the preferred side, and the decision should be based on the quality of the vessels.

- **Vascular mapping by Doppler ultrasound.** This provides information about the venous vasculature, particularly in obese patients and in the upper arm, and about the diameter of the brachial, radial, and ulnar arteries; detects vascular calcifications; and reveals the blood flow volume in the brachial artery. The resistance index, a measure of arterial compliance, can be calculated from the differences between the high-resistance triphasic Doppler signal with clenched fist and the low-resistance biphasic waveform after the fist is released. A preoperative resistance index of 0.7 or higher in the feeding artery indicates insufficient arterial compliance (often associated with arterial calcification) so that the chance of successful creation of an AV fistula is reduced. Current guidelines recommend ultrasound mapping in all patients. Additional angiography is needed only in very difficult cases; the use of radiocontrast media should be minimized.

Preservation of veins during the earlier stages of CKD is crucial for the success of vascular access. Patients should be instructed to protect their veins, restricting blood sampling to the dorsum of the hand whenever possible.

PRIMARY AUTOGENOUS VASCULAR ACCESS

Radiocephalic AV Fistula

A well-functioning distal radiocephalic AV fistula in the non-dominant arm is the ideal permanent access for HD. This usually gives an adequate blood flow and a long length of superficial vein for needling. It also leaves proximal sites for further procedures in the event of failure. A distal radiocephalic AV fistula should be possible in a majority of incident patients but may be compromised if the cephalic and antecubital fossa veins are unusable because of thrombophlebitis from previous intravenous cannulae or venipunctures. For this reason, it is essential that these veins be avoided for intravenous cannulae, which should be restricted to the dorsum of the hand in all patients with CKD, except in the emergency situation when rapid access to the circulation is required.

A radiocephalic AV fistula is usually created at the wrist (Fig. 87.1) but can be performed more proximally in the forearm if distal vessels are inadequate. On occasion, three or four radiocephalic AV fistulas can be created at progressively more proximal sites in the forearm before resorting to a brachiocephalic AV

fistula. The radiocephalic AV fistula at the wrist was initially described by Brescia and Cimino in 1966 as a side-to-side anastomosis, but an end-to-side configuration is preferred by most to reduce the risk of venous hypertension in the radial aspect of the hand. An end-to-end anastomosis is advocated by some surgeons to eliminate the small risk of steal.

The primary patency of radiocephalic fistulas varies from center to center, but recent publications report high primary failure rates varying from 5% to 41% and 1-year primary patencies from 52% to 71% (Fig. 87.2).²⁻⁷ Early thrombosis and nonmaturation of an AV fistula in the older comorbid population, who have poor upper limb vessels, are the major causes of these high primary failure and low patency rates. The patency of radiocephalic AV fistulas is poorer in women, so a proximal AV fistula might be preferable if the cephalic vein or radial artery is small.

Nonmaturation of Radiocephalic AV Fistula

The autogenous radiocephalic AV fistula needs time to mature and for the vein to enlarge to a size at which it can be needled for dialysis. Usually 6 weeks for maturation is advised. Earlier cannulation can damage the thin veins. Nonmaturation rates vary from 25% to 33%. The essential components of a successful AV fistula are a sufficient vein diameter of 4 to 5 mm for needling and a high blood flow so that blood can be drawn from the fistula at between 300 and 400 ml/min. In reality, this requires a fistula flow of about 600 ml/min to prevent excessive recirculation and to permit adequate dialysis within the usual 4-hour time

frame of a HD treatment. Fistulas that fail immediately are the consequence of poor selection of vessels or poor technique. Regular duplex ultrasound investigation early after AV fistula formation, especially in fistulas that are not maturing, can detect poor flow, stenosis, and accessory branches, guiding the interventional radiologist and surgeon to the appropriate treatment.

SECONDARY AUTOGENOUS VASCULAR ACCESS

Although a primary radiocephalic AV fistula is preferable, the first-choice procedure is increasingly an upper arm AV fistula with use of an autogenous deeply located arm vein, especially in the dialysis population with associated comorbidities such as diabetes mellitus, coronary artery disease, and peripheral arterial occlusive disease.¹

The upper limb is preferred to the lower limb for vascular access because of the ease of cannulation, comfort for the patient, and considerably lower incidence of complications. Similarly, autogenous conduits are preferable to the use of prosthetic grafts because of improved patency and lower risk of infection.

Forearm Cephalic and Basilic Vein Transposition and Elevation

Superficial vein transposition or elevation increases the possibilities of creating a forearm fistula. The cephalic vein is preferred, but if it is unsuitable, the basilic vein can be transposed from the ulnar to the radial side along a straight subcutaneous course from the elbow to the radial artery. Alternatively, a basilic vein to ulnar artery anastomosis can be performed with additional volar transposition to facilitate needling for dialysis.

Different surgical techniques, with or without transposition, have been advocated according to the forearm artery and vein location. In one study,⁸ 91% fistula maturation was achieved with a range of techniques; 15% were suitable for a straightforward AV fistula, 33% required vein transposition from dorsal to volar for anastomosis to the appropriate artery, and the remaining 52% required superficial transposition of a vein on the volar aspect of the forearm before arterial anastomosis. Primary patency rates were 84% at 1 year and 69% at 2 years.

Needle cannulation may be difficult, particularly in obese patients. A forearm cephalic vein that is too deeply located may be made accessible for cannulation by transposition or elevation. In one study, the elevation technique was applied in obese patients with radiocephalic AV fistulas and cannulation difficulties; primary failure rate was 15%, with a 1-year patency rate of 84%. After operation, all patients could be successfully cannulated for dialysis.⁹

Elbow and Upper Arm Cephalic Vein AV Fistula

The brachiocephalic and antecubital fistulas are two possible AV anastomoses in the elbow region. In addition, anastomosis between the transposed cephalic vein and brachial artery 2 cm proximal to the elbow may be executed, which provides an optimal situation for cannulation along the cephalic vein (Fig. 87.3). The outcome of the brachiocephalic AV fistula is usually good, with a high primary function rate and good long-term patency; studies showed a 10% early failure rate due to nonmaturation and an 80% 1-year patency rate.^{10,11} Two-year primary, assisted primary, and secondary patency rates were 40%, 59%, and 67%, respectively. (Primary patency is functioning access without any intervention; assisted primary patency is functioning access after preemptive intervention for flow decline; secondary patency is functioning access after intervention for thrombosis.) Predictors of failure include diabetes mellitus and a history of contralateral forearm AV graft (indicating poor vessels). Therefore, the primary patency of brachiocephalic fistulas is

comparable to that of radiocephalic fistulas. The early failure and 1-year patency rates of brachiocephalic AV fistulas are shown in Figure 87.4.¹⁰⁻¹⁴

Upper Arm Basilic Vein AV Fistula

The upper arm basilic vein is usually inaccessible for dialysis cannulation because of its medial and deep position. Therefore, the basilic vein needs to be superficialized and transposed to an anterolateral position. The original technique of brachio-basilic AV fistula construction is a two-step approach. First, a brachio-basilic anastomosis is constructed, and in the second operation, usually after 6 weeks, the arterialized vein is mobilized into a subcutaneous position, becoming accessible for needling (Fig. 87.5); nowadays, the brachio-basilic AV fistula may be performed as a one-stage surgical procedure, with elevation or transposition of the vein to a subcutaneous and anterolateral position at the time of creation of the AV anastomosis. A nonrandomized study comparing the different techniques of brachio-basilic AV fistula

creation reported 86% to 90% 1-year patencies in all groups, with only 5% to 7% nonmaturation rates.¹⁵ Primary failure rates of 2% to 23% with 1-year patencies varying from 55% to 89% have been reported (Fig. 87.6).^{12,16-19} In comparison with brachiocephalic fistulas, brachio-basilic AV fistulas are more likely to mature, although they are more susceptible to late thrombosis. However, a randomized study showed similar patencies of brachiocephalic and brachio-basilic AV fistulas.¹²

The technique of subcutaneous placement of the basilic vein has several advantages over forearm or upper arm graft implantation, with less infection and thrombosis. A meta-analysis

comparing brachio-basilic AV fistulas with prosthetic grafts has shown superiority of the brachio-basilic AV fistula in primary and secondary patency rates, and it should therefore be used early in difficult access cases before the use of prosthetic grafts.²⁰

NONAUTOGENOUS PROSTHETIC VASCULAR ACCESS

When autogenous AV fistula creation is impossible or the fistulas have failed, graft implantation should be considered as a vascular

Figure 87.7 Nonautogenous prosthetic graft (PTFE) vascular access. Straight and loop configuration in upper limb.

access conduit. Xenografts such as the ovine sheep (Omniflow) and bovine cow ureter graft (SynerGraft) are popular materials as an alternative access conduit, with acceptable patency and low infection rates. The most frequently used implants are prosthetic grafts made of either polyurethane (Vectra) or polytetrafluoroethylene (PTFE). These prosthetic grafts can be implanted in a wide variety of locations and configurations in the upper limb (Fig. 87.7). Short-term functional patency is usually good, but stenosis (mostly at the graft-vein anastomosis) may lead to thrombotic occlusion within 12 to 24 months. The primary patency rates of prosthetic AV grafts vary from 60% to 80% at 1 year and from 30% to 40% at 2 years of follow-up. Secondary patency ranges from 70% to 90% and from 50% to 70% at 1 and 2 years, respectively.²¹⁻²⁴ Intimal hyperplasia, with smooth muscle cell migration and proliferation and matrix deposition, is the major cause of stenosis formation and thrombosis. The etiology of the intimal hyperplasia is uncertain, although the high wall shear stress, caused by the access flow, may denude the endothelial cell layer, resulting in platelet adhesion and initiation of a cascade of proteins that stimulate the smooth muscle cells to proliferate and to migrate.

Measures to Improve Graft Patency

Numerous experimental and clinical studies have defined the influence of graft material and graft design on AV graft patency. Modulating the geometry of the arterial inlet or venous outlet of the graft may have a beneficial effect on intimal hyperplasia. Clinical studies using tapered (at the arterial side of the graft) grafts did not improve patency rates, nor did cuff implantation at the venous anastomosis.^{25,26} However, primary patency did improve with the use of a cuff-shaped prosthesis (Venaflow).²⁷ Grafts such as polyurethane, which are more distensible, could in principle influence intimal hyperplasia by the better matching of the stiff prosthesis with the compliant vein at the anastomotic site; however, in clinical studies, this feature was not of proven benefit.²⁸

PHARMACOLOGIC APPROACHES FOR ACCESS PATENCY

Aspirin, ticlopidine, and dipyridamole have some beneficial effect in maintaining patency of AV fistulas and grafts but increase the risk of hemorrhage.²⁹ Clopidogrel may also be effective in reducing thrombosis of AV grafts and fistulas. Warfarin reduces AV graft thrombosis but increases the risk of hemorrhage.³⁰ A recent large trial showed that dipyridamole plus aspirin had a significant but modest effect in reducing the risk of stenosis and improving the duration of primary unassisted patency of newly created AV grafts.³¹ In a large randomized study, clopidogrel improved primary radiocephalic fistula function but not maturation.³² On the available evidence, antiplatelet agents should be used routinely in patients with AV grafts but not fistula. Warfarin should be considered only when there is recurrent thrombosis in the absence of anatomic stenosis.

There have been suggestions that other drugs, such as calcium channel blockers and angiotensin-converting enzyme inhibitors, might be associated with improved AV fistula patency, but this requires confirmation with randomized studies.³³ Fish oil reduced AV graft thrombosis in one randomized trial.³⁴

Efforts have been made to inhibit the development of intimal hyperplasia pharmacologically with the cytotoxic agent paclitaxel. Paclitaxel wraps have been shown to reduce prosthetic graft intimal hyperplasia in animal models but have yet to be clinically evaluated.

LOWER LIMB VASCULAR ACCESS

Probably the only indication for lower limb vascular access is bilateral central venous or caval obstruction, which endangers the outflow of upper limb AV fistulas. Saphenous and superficial femoral vein transposition is a primary option for thigh AV fistulas, although this carries a relatively high risk of distal ischemia. If clinical evaluation indicates incipient ischemia, primary flow

reduction by tapering of the anastomosis is indicated to prevent ischemia.³⁵ Prosthetic graft implantation in the thigh bears a high risk of infection and septicemia.

VASCULAR ACCESS COMPLICATIONS

Nonmaturation of AV Fistulas

Fistulas that fail immediately are the consequence of poor selection of vessels, poor technique, or postoperative hemodynamic instability. Vascular abnormalities, including stenoses, occlusions, and accessory veins, will be identified in virtually all early failures, and more than half of the stenoses are in the perianastomotic area of nonmatured fistulas. Arterial inflow stenoses of more than 50% coupled with poor flows are seen in less than 10% of nonmaturing fistulas, but if identified, they should undergo angioplasty. If this fails to improve fistula flow rates, it is unlikely that surgical bypass will be of help. Anastomotic and swing segment (where the vein has been mobilized and swung over to the artery) stenosis may be treated percutaneously or surgically, depending on local expertise.

The diameter of the angioplasty balloon is chosen to correspond to the diameter of the vessel next to the stenotic or occlusive lesion and is usually not smaller than 5 mm for venous stenoses and not smaller than 4 mm for arterial or anastomotic stenoses. Ultrahigh-pressure balloons inflatable up to 30 atm are used when necessary to abolish the waist of the stenosis on the balloon. Apart from local infection, contraindications to balloon angioplasty are anastomotic stenoses in fistulas less than 4 to 6 weeks after surgical construction, which increases the risk of anastomotic disruption at angioplasty. Percutaneous balloon angioplasty is further discussed in Chapter 88.

The surgical approach is to reconstruct the AV fistula, usually under local anesthesia. The anastomosis is exposed and ligated; the vein can then be divided, mobilized proximally, and reanastomosed to the proximal radial artery.

A prospective nonrandomized study of 64 patients showed that outcomes were similar with angioplasty or surgery.³⁶ Restenosis rates were significantly higher after angioplasty, but overall costs of treatment were similar.

Nonmatured fistulas are rescued by angioplasty of stenoses or occlusions, ligation of accessory veins, or both. Accessory veins can be obliterated through coil embolization, percutaneous ligation, or surgical ligation. The use of coils with a diameter of 1 mm in excess of the target vessel diameter will prevent coil dislocation. Although ligation of accessory veins is usually performed in a single surgical intervention, three variants of vein ligation in a stepped approach have also been described.³⁷ By use of this approach, surgery is limited to ligation of the accessory veins if the AV fistula appears to be of adequate size to allow cannulation. If the fistula is still considered to be too small, the median cubital vein is ligated. If the AV fistula is still believed inadequate, temporary banding of the main venous channel is performed. Apart from surgical ligation, accessory veins can also be ligated percutaneously.

Stenosis and Thrombosis

The development of vessel stenosis in both autogenous AV fistulas and prosthetic AV grafts is usually initiated by intimal hyperplasia due to migrating and proliferating vessel smooth muscle cells, which form extracellular matrix. Progressive stenosis leads to access flow deterioration and subsequently

thrombotic occlusion. Prophylactic repair of access stenoses may prevent thrombosis and prolong access patency.

Autogenous Fistula Stenosis or Thrombosis

AV fistula stenosis should be treated if the vessel diameter is reduced by more than 50% and is accompanied by a reduction in access flow (25% flow decline between measurements or absolute flow below 500 ml/min) or in measured dialysis dose. Other indications for intervention are difficulties in cannulation and prolonged bleeding time after decannulation, indicating high intra-access pressure due to outflow vein stenosis. In AV fistulas, 55% to 75% of the stenoses are close to the AV anastomosis, 25% in the venous outflow tract and 15% in the arterial inflow. In brachiocephalic and brachio basilic AV fistulas, the typical location for stenosis (besides the anastomosis) is at the junction of the cephalic with the subclavian vein and the basilic with the axillary vein (junctional stenosis).

Endovascular treatment by percutaneous transluminal angioplasty (PTA) is the first option for arterial inflow and venous outflow stenoses and junctional stenoses, with the option of stent placement.³⁸ These techniques are discussed further in Chapter 88. Some stenoses may not be sufficiently dilated by conventional balloons (12 to 16 atm), and in these patients, cutting balloons or ultrahigh-pressure balloons (up to 32 atm) may be applied. Anastomotic stenoses in forearm and upper arm fistulas are primarily treated with PTA; however, surgical revision with a more proximal reanastomosis for swing segment stenosis is indicated in failed PTA of radiocephalic AV fistula.

Fistula thrombosis should be treated as soon as possible because timely declotting allows immediate use of the access without the need for a central venous catheter; fistula salvage usually requires intervention within 6 hours (grafts may be salvaged up to 24 hours). The duration and site of AV fistula thrombosis as well as the type of access are important determinants of treatment outcome. Thrombi become progressively fixed to the vein wall, which makes surgical removal more difficult. When the clot is localized at the anastomosis in radiocephalic and brachiocephalic fistulas, the outflow vein may remain patent because of continuing flow in its tributaries, making it possible to create a new proximal anastomosis.³⁹

Thrombolysis can be performed mechanically or pharmacomechanically.⁴⁰⁻⁴² Whereas the immediate success rate is higher in AV grafts than in autogenous AV fistulas (99% versus 93% in forearm fistulas), the primary patency rate of the forearm AV fistula at 1 year is much higher (49% versus 14%). One-year secondary patency rates are 80% in forearm and 50% in upper arm AV fistulas.

In AV fistulas, the combination of a thrombolytic agent (urokinase or tissue plasminogen activator [tPA]) with balloon angioplasty resulted in an immediate success rate of 94%.⁴¹

AV Graft Stenosis or Thrombosis

The most common cause of graft dysfunction and thrombosis is venous anastomotic stenosis. Because grafts should be implanted only in patients with exhausted peripheral veins, vein-saving procedures like PTA or patch angioplasty are preferred to graft extensions to more central venous segments. When a stent or a patch fails, graft extension is still possible. Graft monitoring by access flow measurement is recommended; with preemptive endovascular treatment, this may diminish graft thrombosis but does not extend graft patency.

Intra-graft (or mid-graft) stenoses are found in the cannulation segment of grafts. They result from excessive ingrowth of

fibrous tissue through puncture holes. These stenoses can be treated by PTA, graft curettage, or segmental graft replacement. When only a part of the cannulation segment is replaced, the access can be used for HD without the need of a central venous catheter. When restenosis occurs in a nonexchanged part of the graft, this can be replaced after healing of the new segment.

Prosthetic graft thrombosis can be treated with various percutaneous techniques and tools, including combinations of thromboaspiration, thrombolytic agents such as tPA, and mechanical thrombectomy. An initial success rate of 73% and primary patency rates of 32% and 26% at 1 and 3 months, respectively, are reported.⁴³⁻⁴⁶ It is important to perform thrombolysis as soon as possible to avoid the need for a central venous catheter and as an outpatient procedure to decrease costs, whenever possible. Postprocedural angiography to detect and to correct inflow, intra-access, or venous outflow stenosis is mandatory.

When endovascular treatment fails or is not possible, surgical thrombectomy may be performed with a Fogarty catheter after venotomy, with correction of the underlying obstruction. On-table angiography should be performed after completion of thrombectomy of both the arterial and venous limbs of the graft.

Central Venous Obstruction

In the majority of patients, central vein obstruction is due to previously inserted central venous catheters or pacemaker wires. In 40% of patients with subclavian vein and 10% with jugular vein catheters, venous stenosis or occlusion will develop. Chronic swelling of the access arm is the most important sign, usually with prominent superficial collateral veins around the shoulder. The indications for intervention, by PTA and stent placement, are severe and disabling arm swelling, finger ulceration, and pain or inadequate HD. Contrast angiography of the access and complete venous outflow tract must be performed because the central veins can be difficult to examine with ultrasound in their retroclavicular position.

Endovascular Intervention

Endovascular intervention is the first option for central venous obstruction treatment. PTA alone results in low primary patency rates of 10% or less at 1 year, and numerous restenoses may develop. Primary or additional stent implantation gives much better outcome, with 1-year patency rates up to 56% or more.^{47,48} Reinterventions are usually required to maintain patency and to achieve long-term clinical success.

Stent placement should avoid overlapping the ostium of the internal jugular vein because this vein is essential for future placement of central venous catheters. Similarly, a stent placed in the innominate vein should not overlap the ostium of the contralateral vein; otherwise, contralateral stenosis may occur and preclude future use of the contralateral limb for access creation.

Surgical Intervention

When interventional treatment of central venous obstruction fails, surgical revision with bypass grafting is indicated. Surgical bypass to the ipsilateral jugular vein or contralateral subclavian or jugular vein is the first option in these patients. Alternative surgical approaches for upper limb vascular accesses with compromised venous outflow are axillary vein to femoral, saphenous, or popliteal vein and right atrial bypasses.⁴⁹ In case of bilateral obstruction of the mediastinal veins, including the superior vena

cava, it will not be possible to sustain upper limb access, and lower limb access will be required.

Ultimately, ligation of the upper limb access can be considered, which will relieve local symptoms but loses a valuable dialysis access.

Vascular Access–Induced Ischemia

Vascular access–induced upper limb ischemia is a serious complication that without prompt intervention may lead to amputation. The incidence of symptomatic ischemia varies from 2% to 8% of the HD population.⁵⁰ Elderly patients, diabetics, and patients with peripheral or coronary arterial occlusive disease are most at risk of ischemia. In addition, previous ipsilateral vascular access increases the risk. Access-induced ischemia occurs more often with proximally located fistulas. These high-flow AV fistulas induce a steal phenomenon with lowering of distal perfusion pressures, and when collateral circulation is inadequate, symptoms may occur. Pain during HD is a characteristic early symptom. A grade 1 to 4 classification for access-induced ischemia can be used to outline the severity of the disease; this ranges from minor symptoms to finger necrosis.

Grade 1: pale/blue or cold hand without pain

Grade 2: pain during exercise or HD

Grade 3: ischemic pain at rest

Grade 4: ulceration, necrosis, and gangrene

For grades 1 and 2, ischemia conservative treatment is advocated. With grades 3 and 4, interventional treatment is mandatory.

Diagnosis of Ischemia

Physical examination, including observation and palpation of peripheral vessels, may be inadequate and misleading for the diagnosis of symptomatic ischemia. Additional noninvasive testing with measurement of digital pressures and calculation of the digit to brachial index, transcutaneous oximetry, ultrasound of forearm arteries, and access blood flow measurement are important steps in the diagnosis and decision-making process. Finally, contrast angiography with visualization of the upper extremity arterial tree from the proximal subclavian artery to the distal palmar arches with and without AV fistula compression to enhance distal flow is obligatory to outline the strategy for treatment and to determine whether interventional or surgical options are preferred.

Endovascular and Surgical Management of Ischemia

The treatment strategy depends on the etiology of the ischemia. Inflow arterial obstruction and distal arterial lesions are recanalized with small-caliber balloons or stent placement⁵¹; high-flow AV fistulas are suitable for flow-reducing procedures like access banding (Fig. 87.8) and arterial inflow reduction by an interposition graft to a smaller forearm artery (revision using distal inflow).^{52,53} Steal in itself may be cured by ligation of the artery distal to the arteriovenous anastomosis (distal radial artery ligation). In most patients, it is necessary to add a saphenous vein or prosthetic graft bypass to the forearm arteries to augment distal hand perfusion (distal revascularization and interval ligation; Fig. 87.9). The results of these procedures are usually good, with relief of symptoms and preservation of the access site (Fig. 87.10).⁵⁴⁻⁵⁸ A simpler alternative to the distal revascularization–interval ligation procedure is the proximal arteriovenous anastomosis technique, in which the AV anastomosis at the elbow is disconnected and moved to the axilla, with

Figure 87.8 Surgical techniques for banding of a high-flow vascular access. **A**, Open venoplasty; **B**, Interrupted mattress suturing; **C**, Continuous mattress suturing; **D**, PTFE banding; **E**, PTFE interposition graft. The choice of technique is made by the surgeon on a case by case basis.

anastomosis to the axillary artery by means of a graft interposition.⁵⁹ Recently, the minimally invasive limited ligation endoluminal-assisted revision procedure was described, using a minimally invasive percutaneous technique with banding of the access over a 4-mm balloon.⁶⁰

Intraoperative digital pressure measurement or transcutaneous oximetry (TcPo₂) is mandatory to guarantee an adequate surgical intervention with acceptable outcome. A digital-brachial pressure index above 0.60 or TcPo₂ above 40 mm Hg is indicative of sufficient distal hand perfusion. In some patients, AV fistula ligation and transition to chronic catheter dialysis access or a change in renal replacement modality to peritoneal dialysis may be the only solution.

CENTRAL VENOUS CATHETER ACCESS

Central venous catheters are still widely used as vascular access for HD. Data from the DOPPS study⁶¹ indicate that 25% of HD patients in the United States are dialyzed with catheters; in other countries, the use of catheters is even more common (Belgium, 41%; United Kingdom, 28%). Central venous catheters are the preferred vascular access for patients presenting with acute kidney injury and for chronic patients without permanent AV access or with failed vascular access. Two types of catheters are used in practice: nontunneled catheters for short-term dialysis, with a limited use and high morbidity; and tunneled cuffed catheters, which can be used up to several months or years with low morbidity. The physical characteristics (i.e., design and geometry) not only influence the performance (blood flow rate, recirculation, and resistance) but also affect the overall efficiency of the HD therapy and the morbidity risk (infection, thrombosis).

Nontunneled Catheters

Single- or double-lumen catheters are usually made of polymers (polyethylene, polyurethane), enabling a simple and direct implant possibility. The length of the catheter must be chosen in accordance with the insertion site. The femoral route requires catheters of 30 to 35 cm in length for the distal tip to be located in the inferior vena cava. The internal jugular vein route needs shorter catheters of 20 to 25 cm in length, with tip location at the inferior vena cava–right atrium junction. The subclavian vein should not be used because of the very high risk of subsequent venous stenosis. For sufficient blood flow rates to be achieved, the diameter of these catheters must be ideally between 12 and 14 French. It is recommended that the use of nontunneled catheters not exceed 7 days.

Tunneled Catheters

Tunneled central venous catheters have two lumens, each having a length of 40 cm, 10 cm of which is tunneled under the skin; the cannulae are made of synthetic polymer with a large internal lumen and a Dacron cuff to ensure subcutaneous anchoring. The catheter characteristics rely on the type of polymer, design, and geometry (double-lumen catheters, dual catheters, split catheters). The use of a tunneled central venous catheter is associated with reduced morbidity as well as better and constant performance compared with uncuffed catheters.⁶²

Both tunneled and nontunneled catheters are inserted percutaneously by the Seldinger technique and ultrasound guidance. These techniques are described in Chapter 88. The internal jugular vein (Fig. 87.11) and femoral vein routes are preferred

because of ease of implantation and low risk of complications, such as central vein stenosis.

Catheter Infection

Catheter-related blood stream infections are a significant cause of mortality in HD patients. Results of the HEMO study indicate

that patients with central venous catheters have an increased relative mortality risk of 3.4 compared with patients with AV fistulas. Switching from central venous catheters to AV fistulas decreases the relative mortality risk to 1.4.⁶³ The most likely explanation for this increased mortality risk is infection and sepsis related to the central venous catheter, including exit site infection. Typical infection rates are 3 episodes of infection per 1000 tunneled catheter-days and higher with nontunneled catheters.⁶⁴ These localized infections can progress to metastatic complications of osteomyelitis, septic arthritis, epidural abscess, and endocarditis. Various societies have issued recommendations for the management of catheter infections.⁶⁵ A recommended treatment algorithm is shown in Figure 87.12.

Infections Involving Temporary Catheters

When a temporary dialysis catheter becomes infected, it should always be removed. There is no role for trying to salvage temporary catheters.⁶⁵

Exit Site Versus Tunnel Track Infections

An exit site infection is a localized cellulitis confined to the 1 to 2 cm where the catheter exits the skin. The majority of these cases respond well to systemic antibiotics and meticulous exit site care, and the removal of the catheter is generally not required.⁶⁵ However, exit site infections can progress to tunnel track infections, which involve the potential space surrounding the catheter more than 2 cm from the exit site (Fig. 87.13). Patients with a tunnel track infection sometimes but not always have an associated exit site infection; untreated, they can rapidly develop bacteremia. Patients with a tunnel track infection present with fever as well as local signs of pain, swelling, fluctuance, and erythema along the track of the catheter. Because tunnel track infections involve a potential space, in an area with limited vascular supply, and an implanted synthetic material, they respond poorly to antibiotics alone and require catheter removal.⁶⁵

Catheter-Associated Bacteremia

When a patient with a dialysis catheter has a fever, catheter infection must always be considered. If the patient does not have a clear and convincing alternative explanation for the fever, blood culture specimens should be obtained peripherally as well as through the catheter, and the patient should be started on antibiotic therapy, which is subsequently adjusted on the basis of culture results.⁶⁵ The most common organism is *Staphylococcus*, although a wide range of gram-positive and gram-negative organisms have been reported (Fig. 87.14). The percentage of patients with methicillin-resistant *Staphylococcus aureus* (MRSA) varies greatly between centers, with higher rates associated with

greater antibiotic use. An aminoglycoside or a cephalosporin is a good choice for gram-negative coverage; however, local microbiologic epidemiology must be taken into consideration, especially concerning antibiotic resistance.

Catheter Removal

The decision to remove a tunneled cuffed dialysis catheter for an episode of catheter-associated bacteremia is not straightforward. The clinical condition of the patient and response to initial therapy, the presence of metastatic complications, the infecting

organism, and the availability of other vascular access sites must all be taken into consideration before deciding on a treatment plan (see Fig. 87.12).

The conventional approach is to remove the catheter with interval replacement at a different site after the infection has resolved. Although this is effective, it leads to an additional temporary catheter if dialysis is needed before the catheter can be replaced. Attempts to “salvage” an infected catheter with systemic antibiotic therapy lead to resolution of infection in only about 30% of cases. Another treatment option is to combine systemic antibiotics with antibiotic “lock” solutions. Many different cocktails of antibiotics mixed with either heparin or citrate have been tested; a popular regimen is vancomycin 2.5 mg/ml, gentamicin 1 mg/ml, and heparin 2500 U/ml. Infection clearance rates of between 50% and 70% are reported with antibiotic locking.

Several studies have reported that exchange of the catheter over a guide wire 48 hours after initial antibiotic treatment is more effective than treatment with antibiotics alone and is as effective as removal of the catheter and delayed replacement, with the advantages of only one invasive procedure and preservation of the venous access site. Randomized trials of antibiotic locking and catheter exchange over a guide wire are not yet available.

Prevention of Infection

The most important measure to prevent catheter infection is meticulous handling of the catheter at all times. The catheter should be inserted with use of maximal sterile precautions. The dialysis nurses need procedures for accessing the catheters under strict sterile conditions, and it is of the utmost importance that these catheters are never accessed by untrained personnel. Preliminary data suggest that antibiotic lock solutions significantly reduce the incidence of infection, but large randomized trials demonstrating both safety and efficacy are awaited before this can be recommended. Topical application of mupirocin

ointment to tunneled exit sites has been reported to reduce the incidence of catheter-associated bacteremia.

Catheter Obstruction

Catheter obstruction may be due to endoluminal fibrin deposits, restricting the catheter lumen or obstructing catheter side holes at the tip, or external fibrin sleeves surrounding the catheter, resulting in inadequate flow and excessive extracorporeal blood pressure alarms during the dialysis session. Depending on the location of the fibrin clot (arterial or venous line), there may be high negative arterial pressure (obstruction at the arterial catheter line) or high positive venous pressure (obstruction at the venous catheter line).

Prevention of clot formation in the catheter tip during the interdialytic period is crucial. This is achieved by installing an antithrombotic lock solution (sodium citrate is superior to standard heparin or low-molecular-weight heparin). A certain amount of the antithrombotic lock solution may leak into the circulation through side and central catheter holes, facilitating

catheter clot formation while increasing risk of hemorrhage. Regular use of low-dose warfarin or antiplatelet agents has failed to improve catheter function in dialysis patients in randomized trials.

To prevent or to correct catheter dysfunction, it is recommended that the catheter lumen be cleaned periodically by applying a fibrinolytic agent (urokinase or tPA) as a lock solution or by continuous infusion on both arterial and venous lines. Occluded catheters are reopened either by means of a mechanical method (brush) or pharmacologically (urokinase or tPA). Removal of the fibrin sleeve may be achieved by lasso wire stripping or by infusion of a fibrinolytic solution (urokinase, tPA) during 3 to 6 hours. Alternatively, the catheter may be exchanged over a guide wire.

Diagnostic and Interventional Nephrology

W. Charles O'Neill, Haimanot Wasse, Arif Asif, Stephen R. Ash

A variety of procedures are essential to the care of nephrology patients and include ultrasound, renal biopsy, insertion of hemodialysis and peritoneal dialysis (PD) catheters, creation of arteriovenous (AV) fistulas, and diagnostic and interventional procedures on hemodialysis accesses. These procedures have traditionally been performed by other specialists, and this may lead to fragmented care. The desire to provide more continuity of care has led an increasing number of nephrologists to perform these procedures, the field of diagnostic and interventional nephrology. It is most developed in the United States, where the American Society of Diagnostic and Interventional Nephrology (www.asdin.org) has established training standards and certification procedures. This chapter covers ultrasound, insertion of dialysis catheters, and interventions on vascular access, focusing on their applications and their performance by nephrologists. Renal biopsy is covered in Chapter 6, placement of AV fistulas and AV grafts in Chapter 87.

ULTRASOUND

An important reason for nephrologists to be involved in this procedure is that many of the findings on ultrasound are not specific and require clinical correlation. The role and interpretation of ultrasound are further covered in Chapter 5.

Applications and Limitations of Ultrasound

Ultrasound is an excellent tool for examination of the kidneys and urinary tract. Under optimal conditions, both kidneys, the renal artery and vein, the proximal and distal ureter (when enlarged), and the bladder can be visualized. The ureter is usually apparent only when it is dilated. The middle portion of the ureter is usually obscured by overlying bowel but still may be visible when it is very dilated. In transplants, the entire ureter can be visualized, even when it is not markedly dilated, because of the proximity to the probe and the lack of overlying bowel. In very ill patients who cannot be optimally positioned or cannot control their breathing or have abdominal wounds or distention, views of the kidneys may be limited, but it is still possible in most of these patients to determine whether hydronephrosis is present.

Chronic Kidney Disease

Ultrasound is indicated in any patient presenting with chronic kidney disease (CKD) to establish renal size and to rule out polycystic kidney disease or urinary tract obstruction. Small, echogenic kidneys indicate severe irreversible disease, eliminating the need for a biopsy.¹

Acute Kidney Injury

Although the diagnostic yield is very low in patients in whom the basis for renal failure is likely to be acute tubular necrosis or prerenal causes, ultrasound is still indicated in certain patients to rule out obstruction and to identify preexisting CKD.²

Renal Transplant

Ultrasound is indicated when there is an acute decline in renal transplant function because urinary obstruction is common in this setting.³ In the immediate post-transplantation period, Doppler evaluation of renal blood flow should also be performed to rule out thrombosis. Additional indications in transplant patients are pain, swelling, ipsilateral leg edema, and infection. Another important indication in both native and transplanted kidneys is guidance for percutaneous biopsy, nephrostomy, or drainage of fluid collections.

Renal Biopsy

Ultrasound is the method of choice to guide percutaneous renal biopsy.⁴ Except in rare cases, computed tomography offers no advantages over ultrasound⁵ and results in unnecessary irradiation. This is discussed further in Chapter 6.

Urinary Bladder

Ultrasound is the procedure of choice for measurement of post-void residual volume because it is painless and sufficiently accurate⁶ and, when a scanner is readily available, a simple task. Additional indications include checking the location and patency of Foley catheters and examination of the distal ureters. Placement of the catheter in the proximal urethra is uncommon but not rare, and obstruction of catheters is frequent, so examination of the bladder should always be considered when urine output decreases. Prostatic hypertrophy, prostatitis, bladder carcinoma, mucosal edema, blood clots, stones, stents, and other foreign bodies can be recognized by ultrasound, but transabdominal ultrasound is not the appropriate test to rule out bladder cancer (which requires cystoscopy) or prostatic cancer (which requires transrectal ultrasound and biopsy).

Hemodialysis Access

Ultrasound is essential in the management of vascular access, including guidance of catheter insertion, evaluation of fistula dysfunction, preoperative vein mapping, and monitoring of access flow. Of these, the first two can be readily performed by nephrologists. Guidance of catheterization is best performed with a dedicated scanner but can be done with any scanner that has a vascular probe and does not require Doppler imaging.

Examination of dysfunctional fistulas is also straightforward and does not necessarily require Doppler analysis. Vein mapping and monitoring of access flow are both best performed by an experienced vascular technician.

Renovascular Ultrasound

Doppler ultrasound of renal arteries and veins is a difficult study requiring an experienced operator and is not usually practical for nephrologists. Tracings from segmental arteries are more easily obtained and can be useful in diagnosis of renal vein thrombosis. However, measurement of resistive index can be unreliable (it can be influenced by external factors such as systemic blood pressure and heart rate) and is of questionable clinical utility. Doppler ultrasound is also useful in distinguishing between cystic and vascular lesions and between renal vein and ureter.

Equipment

Important considerations in the choice of equipment are image quality, probe type and frequency, cost, size, portability, and output. Image quality is difficult to quantitate and is related to the number of elements (crystals) in the probe and the number of channels that can be processed. Probes should be electronic and in the frequency range of 2.0 to 5.0 MHz (up to 7.5 MHz for pediatric use) for abdominal imaging. Preferably, these should be variable frequency, curvilinear probes. Probes for vascular imaging are usually linear probes with a frequency between 7.5 and 12 MHz. For gray-scale renal ultrasound, portable, lightweight scanners with good image quality are available; Doppler capability can add to the cost but is increasingly being offered as a standard feature. Larger and more expensive scanners are difficult to maneuver and have additional features that are of little use to the nephrologist. Controls on the scanner allow adjustment of scanning depth, focal length, time-gain compensation, sound intensity, and gray scale. Although this seems a daunting number of variables, adjustment is usually straightforward and mostly empirical. Images can be printed directly or digitally stored.

Procedure

Description of the scanning procedures cannot substitute for hands-on training because scanning is an acquired skill that requires practice. Ideally, the patient should be fasting for abdominal scanning to minimize interference from intestinal gas, but this is not essential for examination of kidneys and of no consequence for examination of the bladder or transplanted kidneys. There must be an airtight connection between the probe and the skin, which is accomplished by placing gel on the probe or skin and applying firm pressure against the skin. To avoid compression of the vessels, minimal pressure should be applied for vascular examinations, with the use of more gel. Gel specifically designed for ultrasound should be used because other gels, such as lubricating gel, give poorer image quality. Ambient light should be dimmed to optimize viewing of the monitor.

The patient should be flat in the supine or lateral decubitus position with imaging through the abdomen for examination of native kidneys. Initial attempts should be made in the supine position before resorting to the lateral decubitus position. Imaging through the back is not recommended for diagnostic imaging because of sound attenuation by muscle and fascia and limitations on angling of the probe. Placement of the ipsilateral arm over the head, removal of pillows from under the head, and

deep inspiration aid in moving overlying ribs superiorly. Transplanted kidneys and the urinary bladder are examined in the supine position, but the patient need not be completely flat.

Initially, longitudinal images should be obtained to determine maximal kidney length. On the right side, this view should be obtained through the liver if possible (Fig. 88.1A). The probe should be oriented so that the upper pole is toward the left-hand side of the image. The probe should then be rotated 90 degrees to obtain transverse views (Fig. 88.1B), and the kidney is scanned from pole to pole to ensure visualization of the entire kidney. Examination of each kidney should include longitudinal images with adjacent liver or spleen if possible as well as transverse images through the mid kidney and each pole.⁷ Measurements other than length are of no clinical utility, and measurements of kidney volume are inaccurate and no better than length in judging kidney size.⁸ Sagittal and transverse views of the urinary bladder are obtained with the probe just superior to the symphysis pubis and angled inferiorly (Fig. 88.1C, D). Volume is obtained by multiplying the two transverse dimensions and the sagittal length by 0.523.⁶ The technique for renal biopsy is discussed in Chapter 6.

Training and Certification

There are no data on what constitutes adequate training for renal ultrasound. Training is required for both performance and interpretation and should include didactic, hands-on, and supervised components. The last can vary considerably, depending on case volume and particularly type because any quantity of studies will be inadequate if they are all normal. Thus, the number of studies required for competence is inversely related to the frequency of pathology. Minimal qualifications for physician-sonographers have been established by the American Institute of Ultrasound in Medicine⁹ and the American College of Radiology,⁶ but neither organization has developed guidelines for limited abdominal ultrasound. The American Society of Diagnostic and Interventional Nephrology (www.asdin.org) has established training standards for ultrasound limited to kidneys and bladder that specify 50 hours of training and 125 studies (at least 80 being supervised and the remaining having confirmatory follow-up).¹⁰ Because renal ultrasound is not usually a formal component of nephrology training, a course for nephrologists has been established in the United States (www.medicine.emory.edu/divisions/renal/ultrasound).⁷ Training and certification are available in vascular ultrasound but are not limited to applications specific to nephrology. Such training is important for vascular studies of kidneys but not necessary for examination of dysfunctional AV fistulas and grafts (unless flow is measured) because this does not require Doppler analysis. There are currently no guidelines or training established for vascular ultrasound related to nephrology.

PERITONEAL DIALYSIS CATHETERS

Successful PD is dependent on proper catheter insertion and management. The feasibility, safety, and success of these procedures when they are performed by nephrologists have been well documented,¹¹⁻¹³ and this leads to greater use of PD. Chronic PD catheters are constructed of silicone rubber with a 5-mm external diameter and internal diameters of 2.6 to 3.5 mm. Some commonly used designs of PD catheters are shown in Figure 92.6. The intraperitoneal portion can be straight, straight with perpendicular silicone disks, or curled with side holes or T shaped with linear grooves or slots rather than side holes. These

Figure 88.1 Imaging planes for renal and bladder sonography. **A**, Longitudinal image of right kidney. Upper pole should be on left side of the image. **B**, Transverse image of right kidney through the renal hilum. **C**, Transverse image of urinary bladder. Anteroposterior and mediolateral dimensions are obtained in this plane. **D**, Sagittal image of the urinary bladder. Superior portion of the bladder is to the left. Superoinferior dimension is obtained in this plane.

designs are created to diminish outflow obstruction. The subcutaneous portion is either straight or bent and has one or two extraperitoneal Dacron cuffs that prevent fluid leaks and bacterial migration around the catheter. The subcutaneous catheter shapes all provide a lateral or downward direction of the exit site. An upwardly directed exit site collects debris and fluid, increasing the risk of exit site infection. Currently, the method of placement of the catheter has more effect on the outcome than catheter choice does.

Catheter Insertion

The four techniques for PD catheter insertion are dissection (surgical), the Seldinger technique (blind or with fluoroscopy), peritoneoscopic, and laparoscopic.¹⁴ The Seldinger and peritoneoscopic techniques are most frequently used by nephrologists. Peritoneoscopic insertion is a single-puncture technique using a small (2.2-mm diameter) optical peritoneoscope for direct inspection of the peritoneal cavity and identification of a suitable site for the optimal intraperitoneal portion of the catheter. Peritoneoscopic placement is usually performed with local anesthesia (sometimes with conscious sedation) and manual infusion of about 1 liter of air. Laparoscopic techniques are performed under general anesthesia, with larger scopes, multiple insertion sites, and automated gas infusion. Both peritoneoscopic and laparoscopic techniques allow direct visualization of intraperitoneal structures.

The choice of technique must take into account the local experience with complications (pericatheter leakage, outflow failure, exit site and tunnel infection) and long-term catheter function associated with each technique, costs, ease and timely insertion of the catheter, and factors contributing to mortality risk (local versus general anesthesia). Both randomized and non-randomized studies have documented that the peritoneoscopic and fluoroscopic Seldinger techniques result in fewer catheter complications (infection, outflow failure, pericatheter leak) and improved catheter survival compared with surgical placement.^{12,15} The superior results with peritoneoscopic placement may relate to direct visualization of the abdominal cavity, less tissue dissection, and avoidance of general anesthesia. Because tissue dissection is minimal, the catheter can be used immediately (after 36 hours), although a 2- to 3-week delay is recommended.¹⁶

For peritoneoscopic insertion (Fig. 88.2), a small skin incision (2 to 3 cm) is made and dissection is carried down only to the subcutaneous tissue. The anterior rectus sheath is identified but not incised. A preassembled cannula with trocar and a spiral sheath is then inserted at a 40°-50° angle into the abdominal cavity through the rectus muscle (Figs. 88.2A and 88.3). The trocar is then removed and replaced by the peritoneoscope to confirm the intra-abdominal position of the cannula (Figs. 88.2B and 88.4). Air is then infused (600 to 1000 ml) to separate visceral and parietal peritoneum. Alternatively, a Veress needle can be used.¹⁷ Bowel loops, the dome of the bladder, and any intra-abdominal adhesions are identified. The cannula and spiral

Figure 88.3 Peritoneoscopic insertion of a peritoneal dialysis catheter. During peritoneoscopic insertion of a peritoneal dialysis catheter, a Quill guide trocar and cannula (arrow), with its wrapped spiral sheath, is being inserted through the rectus muscle under local anesthesia.

Figure 88.4 Peritoneoscopic insertion of a peritoneal dialysis catheter. A peritoneoscope has been introduced into the abdominal cavity through the cannula, and the fiberoptic light source is being connected to the scope.

sheath are advanced into the pelvis (Fig. 88.2C). The cannula and the peritoneoscope are then removed, the spiral sheath is dilated to 6-mm diameter (Fig. 88.2D), and the catheter is inserted through the sheath by a stylet (Fig. 88.2E). The deep cuff is implanted into the rectus muscle with use of an implanter tool without dissection of the anterior rectus sheath or the muscle (Fig. 88.2F). A tunnel and an exit site are created (Fig. 88.5), and the superficial cuff is implanted into the subcutaneous tissue. The subcutaneous tissue is sutured with absorbable material; the skin is closed with nylon. No sutures are placed on the external rectus sheath or at the skin exit site.

The Seldinger technique using fluoroscopy begins with blunt dissection down to the level of the lateral border of the rectus sheath. A 22-gauge needle from a 5-French micropuncture set is inserted at an angle of 45 degrees, directed toward the lower

Figure 88.5 Peritoneoscopic insertion of a peritoneal dialysis catheter. With use of a disposable tool, a subcutaneous tunnel is created for the catheter. The superficial cuff shown will be implanted in the subcutaneous tunnel.

pelvis into the peritoneum (ultrasound can be helpful). The location of the needle within the peritoneal cavity is confirmed by injecting 3 to 5 ml of contrast material, which is seen surrounding bowel loops. A micropuncture 0.018-inch wire is then inserted through the needle under fluoroscopy. Once it is in the lower pelvis, a 5-French catheter is placed over the wire. Contrast material can again be injected to confirm the position. A 0.035-inch guide wire is then passed through the catheter, and dilators are advanced sequentially up to the final 18-French dilator and peel-away sheath. The guide wire is removed and the PD catheter is inserted over a metal stylet through the sheath, splitting the sheath as the deep Dacron cuff advances. This cuff is pushed into the rectus muscle while the sheath is in place, and the sheath is then removed around the cuff and catheter. The catheter is tunneled laterally with a tunneling tool.^{18,19}

Burying the Peritoneal Dialysis Catheter

If the catheter will not be used immediately, it can be implanted (buried) under the skin for weeks to months before it is tunneled to the outside and used. The placed in the usual manner, then blocked with a plug and tunneled in a straight line under the skin. Some centers tie off the catheter with silk suture and coil it into a pouch under the exit site. This allows ingrowth of tissue into the cuffs of the catheter without an opportunity for bacterial colonization and diminishes the incidence of early pericatheter infections.^{20,21} Catheters buried in this fashion have been successfully used more than 1 year after insertion.²² We recommend burial when the catheter will not be used for at least a month.

Complications of Peritoneal Dialysis Catheter Insertion

Bowel perforation is the most feared complication of catheter insertion. The incidence is 1% to 1.4% with surgical insertion^{12,13} but 0% to 0.8% with the peritoneoscopic insertion.^{11,13} The diagnosis is established by direct peritoneoscopic visualization of bowel mucosa, bowel contents or hard stool, return of fecal material, or emanation of foul-smelling gas through the cannula. Whereas some investigators suggest that this

complication should be treated with surgical intervention,²⁴ successful conservative management of bowel perforation with bowel rest and intravenous antibiotics has also been reported.^{19,25} To minimize the risk of perforation, a needle (such as a Veress needle) that is smaller and has a blunt, self-retracting end can be used instead of a trocar to gain access to the abdominal cavity.¹⁷ Previous abdominal surgery is mentioned as a relative contraindication to PD because of intraperitoneal adhesions.^{26,27} However, with peritoneoscopy, which can identify intraperitoneal adhesions, assess their extent, and locate a suitable site for catheter placement, the incidence of bowel perforation is no higher than in patients without prior abdominal surgery, and the success rate exceeds 95%.^{11,13}

Catheter Repositioning

Migration of the PD catheter to the upper abdomen is a frequent cause of catheter failure. A variety of techniques have been used for repositioning, including guide wire or stylet insertion, Fogarty catheters, and laparoscopy, and are feasible for nephrologists. The long-term success rate is only 27% to 48%,^{28,29} probably because the migration of the catheter is the result of encasement by the omentum. Thus, insertion of a new catheter is required in many cases. Fogarty catheter manipulation is perhaps the most cost-effective, safe, and simple method. A Fogarty catheter is advanced into the PD catheter, and the balloon is inflated. Manipulation is performed by tugging movements to reposition the catheter into the pelvic area. Infusion and drainage of dialysate as well as radiography are performed to determine patency and position of the PD catheter, respectively.

Removal of Peritoneal Dialysis Catheters

A Tenckhoff curled or straight PD catheter can be safely removed without need for an operating room or general anesthesia.¹⁶ Local anesthetic is infiltrated at the site of the primary incision, and dissection is carried down to the subcutaneous portion of the catheter by longitudinal incisions with scissors while the catheter is held with toothed forceps. The catheter is clamped with a hemostat, a nylon suture is placed in the catheter beyond the hemostat as a tag, and the catheter is cut between the two. Dissection is continued toward the deep cuff (Fig. 88.6), and additional anesthetic is infiltrated around the deep cuff. For catheters that have been in place for less than a month, blunt dissection is usually sufficient to free the deep cuff. Older catheters require sharp dissection. Exposure of the deep cuff and the anterior rectus sheath is required. Once the deep cuff is separated from the surrounding tissue, the intraperitoneal portion of the catheter is gently withdrawn from the peritoneal cavity, and the defect in the rectus sheath is closed with an absorbable purse-string suture. The nylon tag is then pulled to expose the remaining subcutaneous portion of catheter segment, and dissection is performed in the direction of the superficial cuff. Once the superficial cuff is free, this portion of the catheter is removed through the primary incision site or the exit site. Absorbable suture material is used to close the subcutaneous tissue; nylon is used to close the skin. The exit site is not sutured.

Training and Certification

The American Society of Diagnostic and Interventional Nephrology has established training guidelines and criteria for

Figure 88.6 Peritoneal dialysis catheter removal. The catheter (arrow) has been exposed by dissection of the subcutaneous tunnel.

certification of physicians in the insertion of PD catheters (www.asdin.org).¹⁰ In addition to appropriate didactic training, there should be two practice insertions (into models, animals, or human cadavers), observation of two insertions into patients, and then six successful insertions into patients as primary operator.

TUNNELED HEMODIALYSIS CATHETERS

Central venous catheters are used as a temporary hemodialysis access, as a bridge to AV fistula or graft use, and when all other permanent access sites have been exhausted. Nontunneled catheters are used when a limited number of dialysis sessions are anticipated or there are contraindications to tunneled catheters (systemic infection, risk of bleeding) and are appropriate for use only in the inpatient setting. Tunneled catheters can be placed in both inpatient and outpatient settings, can be inserted at multiple vein locations, are relatively low in cost, and provide immediate access. However, there are significant disadvantages, including morbidity due to infection and thrombosis and risk of central vein stenosis or occlusion.^{30,31} The role of the tunneled dialysis catheter in the provision of vascular access for hemodialysis is discussed further in Chapter 87.

Catheter Insertion

The right internal jugular vein is the preferred catheter location compared with the left internal jugular and subclavian vein sites; it provides a straight route to the right atrium, thereby reducing the risk of central vein stenosis. Catheters may also be placed in the femoral veins.

Catheter insertion is performed in a sterile setting, ideally in an operating room environment with fluoroscopy available or at a minimum in a dedicated procedure room with cardiac monitoring. Before cannulation, the vein should be located by ultrasound to detect anatomic variation or venous thrombosis. The patient's neck is then prepared and draped in sterile fashion; under ultrasound guidance, the vein is cannulated with a micropuncture needle (18- to 22-gauge), and a micropuncture guide wire is inserted and positioned in the superior vena cava. The needle is then removed, and the micropuncture dilator is inserted over the guide wire so that it can be replaced with a standard guide wire. The use of the smaller needle rather than the standard 15-gauge

Figure 88.7 Insertion of a venous catheter for hemodialysis. Chest radiograph confirming that the tip of the catheter (arrow) is at the junction of the superior vena cava and the right atrium.

needle minimizes trauma to the vein. A small subcutaneous incision is made adjacent to the dilator or guide wire, additional dilation is performed, and the catheter is placed over the guide wire with care taken to hold the guide wire in place. If a tunneled catheter is to be placed, a catheter exit site is selected inferior to the clavicle and sufficiently lateral to the venotomy to avoid a kink in the catheter. A 1-cm superficial incision is made at this point, and a subcutaneous track adjacent to the venotomy is infiltrated with lidocaine. A double-lumen catheter, generally 28 or 32 cm in length, is attached to the tunneling device and pulled through the subcutaneous tunnel in a curved path. A guide wire is passed through the dilator and into the inferior vena cava. The venotomy site is then serially dilated over the guide wire. The catheter can then be inserted over the guide wire through the venous port. When a split-tip catheter is used, the guide wire is passed in and out of the two venous ports and through an arterial port or through a hollow intracatheter stiffener. Alternatively, a peel-away sheath is placed over the guide wire and the catheter inserted through the sheath after the removal of the guide wire; however, this method has greater potential for blood loss and air embolism. Fluoroscopy is used to confirm tip placement at the level of the right atrium, with the arterial port facing away from the atrial wall, and to ensure that there are no kinks in the catheter (Fig. 88.7). Each port of the catheter is then flushed with saline and locked with the appropriate amount of heparin based on catheter length and priming volume designation, followed by placement of the catheter hub caps.

Catheter Dysfunction

Catheter dysfunction is defined as the failure to maintain a blood flow sufficient to perform hemodialysis without significantly extending treatment time; this is usually 300 ml/min.³⁹ Causes of immediate dysfunction include a kink in the catheter, incorrect position or orientation (arterial port against the vessel wall), and errant venous cannulation. These problems should be

Figure 88.8 Fibrin sheath on a tunneled venous catheter. Contrast material has been injected into a tunneled catheter after the tip (arrow) has been pulled back into the innominate vein. The contrast material fills a sheath that extends from the catheter tip.

ascertained and corrected at the time of catheter placement. Catheter thrombosis is the most common cause of late dysfunction. Extrinsic thrombosis is less common than intrinsic thrombosis and is caused by central vein, mural, or right atrial thrombosis. Intrinsic obstruction results from thrombus within the catheter lumen or tip or most commonly from a fibrin sheath. Fibrin sheaths typically develop weeks to months after catheter insertion and result when a sleeve of connective tissue forms at the venotomy site and extends and encases the catheter tip, creating a flap-valve. First-line treatment of catheter thrombosis includes forceful flush of the catheter with saline. If flow is not restored, a fibrinolytic agent should be instilled. Tissue plasminogen activator (tPA) is commonly used and appears more effective than urokinase in restoring patency and adequate flow.^{32,33} Typically, 2 mg of tPA is instilled into the occluded catheter lumen and allowed to dwell 30 minutes. If this fails, the catheter should be exchanged. Strategies to minimize dialysis catheter thrombosis are discussed in Chapter 87.

Catheter Exchange and Fibrin Sheath Removal

Catheter exchange over a guide wire is useful in the setting of catheter thrombosis or bacteremia and allows the preservation of the venotomy, tunnel, and exit sites. The tunnel and exit sites must appear free of infection if the same sites are to be used. Catheter exchange should take place within 72 hours of the initiation of antibiotic therapy.³⁹ Under sterile conditions, the exit site is anesthetized and the cuff is freed. Once the catheter is pulled back 8 to 10 cm, contrast material is injected through the catheter under fluoroscopy to check for a fibrin sheath (Fig. 88.8). To obliterate a sheath, a guide wire is passed down the venous port of the catheter and into the inferior vena cava. The catheter is then removed, and a balloon catheter is inserted over the guide wire to the sheath location and inflated to disrupt the sheath. The guide wire is then wiped with povidone-iodine (Betadine), and a new catheter is inserted over the guide wire.

When the catheter tip is beyond the venotomy site, near the superior vena cava, contrast material can be injected again to check for sheath removal before proceeding with catheter insertion.

Training and Certification

The American Society of Diagnostic and Interventional Nephrology guidelines for hemodialysis vascular access procedure certification specify formal didactic training in central venous anatomy, sonographic examination of central veins, fluoroscopy, and catheter design and complications. In addition, practical training for certification includes satisfactory insertion of 25 tunneled long-term catheters. More information may be obtained at www.asdin.org.

PROCEDURES ON ARTERIOVENOUS FISTULAS AND GRAFTS

The most common indications for intervention are inadequate flow during dialysis, thrombosis, and failure of AV fistulas to mature. Specific interventions include angiography, thrombectomy, angioplasty, and stenting. All of these procedures require a dedicated facility, either inpatient or outpatient, with fluoroscopy, monitoring equipment, and staff to assist with the procedures and to deliver conscious sedation. There are many different techniques for AV access procedures and few data to indicate superiority of one method over the other, so the choice is generally one of personal preference and cost. However, the first step should always include a careful physical and ultrasound examination of the access. An examination will generally identify the problem and allow detection of access infection, an absolute contraindication to intervention. Appropriate intervention can then be planned. Monitoring and management of vascular access to minimize stenosis, thrombosis, and failure are discussed further in Chapter 87.

Percutaneous Balloon Angioplasty

Stenosis in AV grafts and fistulas is routinely managed by percutaneous balloon angioplasty, which can be safely performed on an outpatient basis, causes minimal discomfort, and allows immediate use of the access. Not all stenotic lesions are responsive, however, and some require repeated treatment. In fistulas, the stenosis is most commonly located at the “swing point,” the portion of the native vein mobilized during creation of the AV anastomosis (Fig. 88.9); in grafts, the venous anastomosis is the most common site of stenosis.³⁴⁻³⁸ Angioplasty is indicated if the stenosis is 50% or more and is associated with clinical or physiologic abnormalities.³⁹ Treatment of stenosis increases access blood flow and longevity, reduces access thrombosis, and reduces vascular access–related hospitalization.^{38,40,41} A relative contraindication to angioplasty is a newly created access (<4 to 6 weeks old).

The access is cannulated with an introducer needle, a sheath is inserted, and initial angiography is performed. This should include views of the access, draining veins (peripheral and central), and arterial anastomosis and is used to confirm the location and degree of stenosis. Unless it is contraindicated, sedation and analgesia are then given with short-acting agents once a lesion has been identified on initial angiography, as angioplasty is painful.

Figure 88.9 Juxta-anastomotic stenosis in a radiocephalic arteriovenous fistula. Contrast material was injected at the arterial anastomosis (bottom left of image) and demonstrates a narrowing in the initial portion of the fistula (arrow).

Figure 88.10 Arteriovenous graft stenosis. **A**, Stenosis in the outflow vein of an upper arm AV graft (arrow). **B**, Angiogram performed immediately after percutaneous angioplasty.

A guide wire is passed through the sheath and across the stenosis. An angioplasty balloon catheter is passed over the guide wire, positioned at the stenotic site, and inflated with a syringe to 18 to 20 atm (Fig. 88.10). A variety of sheaths, guide wires, balloon sizes, and maximum pressures are available. The guide wire is left in place, and angiography is repeated to identify residual stenosis or any complications. Angioplasty is repeated for residual stenosis or when multiple lesions are present and may require a second cannulation of the access in the opposite direction for inflow stenoses. After removal of all devices, hemostasis at the cannulation site is achieved by manual pressure or suture placement. There is no evidence to support the use of antiplatelet agents or anticoagulation after intervention.

According to Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines, a successful angioplasty is achieved when there is no more than 30% residual stenosis and physical indicators of stenosis have resolved.³⁹

Percutaneous Thrombectomy

There are a variety of techniques for thrombus removal. Thromboaspiration is the least costly and is as effective and efficient as mechanical and pharmacomechanical thrombolysis, in which low-dose tPA is instilled into the thrombosed access, the clot is manually macerated, flow returns, and angioplasty is used to dilate access stenoses.⁴² Thrombectomy by thromboaspiration combines angiography with balloon angioplasty and thrombectomy by clot aspiration. Absolute contraindications to thromboaspiration include access infection and known right-to-left cardiac shunt; relative contraindications include a large clot burden and long-standing access occlusion.

The access is cannulated in an antegrade direction, and a guide wire is passed to the level of the central veins. A straight catheter is inserted over the wire to the central veins, and angiography is performed to confirm central venous patency. Anti-coagulation and short-acting sedative and analgesic medications are administered in the central circulation. An angiogram is then obtained as the catheter is pulled back to identify the location of stenosis. The guide wire is then inserted beyond the stenotic lesion, followed by an angioplasty balloon catheter. The balloon catheter is insufflated by hand with a syringe, and the stenotic lesion is dilated. The access is then cannulated in the retrograde direction, a sheath is inserted, and a Fogarty catheter is passed across the arterial anastomosis, inflated, and pulled back through the entire length of the access while clot fragments are aspirated. On return of flow through the access, angiography is performed to evaluate the inflow and the arterial anastomosis, and angioplasty is repeated if necessary. Hemostasis is achieved by manual pressure or a suture at the cannulation sites.

Stents

The precise role of the endovascular stent in AV fistulas and grafts has not been defined. Results from nonrandomized studies differ as to the patency benefit of primary stent use versus angioplasty alone within a stenotic access or central vein.⁴³⁻⁴⁶ Stents are expensive and have often been used in situations in which their use will not extend the life of the access. Stents should be considered in the setting of failed balloon angioplasty (an elastic lesion), when there are few remaining access sites, if the patient is not a surgical candidate for a new access, or when an outflow vein ruptures after balloon angioplasty (Figs. 88.11 and 88.12).^{47,48} Finally, a stent may be useful in the setting of an expanding pseudoaneurysm.^{49,50}

Figure 88.12 Treatment of vein rupture with an intraluminal stent. A, Placement of the stent (arrow). B, An angiogram obtained after stent placement showing that venous outflow has been re-established. (Courtesy Dr. G. Beathard, Austin, Texas, USA.)

Training and Certification

The American Society of Diagnostic and Interventional Nephrology guidelines for hemodialysis vascular access procedure certification specify didactic training in venous anatomy, fluoroscopy, procedural equipment, and sedation and analgesia. Requirements for practical training include 25 cases in both fistulas and grafts of each of the following: angiography, angioplasty, and thrombectomy as primary operator (refer to www.asdin.org for more information). In general, several times that number as secondary operator will be required to become a primary operator.

Hemodialysis: Principles and Techniques

Peter Kotanko, Martin K. Kuhlmann, Nathan W. Levin

Despite the widespread use of peritoneal dialysis and renal transplantation, hemodialysis (HD) remains the main renal replacement therapy in most countries worldwide. More than 1.7 million patients are currently treated with HD in about 28,500 dialysis units worldwide. The HD population is projected to grow to 2.0 million in 2010. Despite significant advances in our understanding of the biology of chronic kidney disease and the risk factors for poor outcome on HD and improved dialysis technology, the annual mortality in HD patients varies from 10% to 25% internationally, depending on demographic and possibly genetic factors.

DIALYSIS SYSTEM

The aim of the HD system is to deliver blood in a fail-safe manner from the patient to the dialyzer, to enable an efficient removal of uremic toxins and fluid, and to deliver the cleared blood back to the patient. The main components of the dialysis system are the extracorporeal blood circuit, the dialyzer, the dialysis machine, and the water purification system.¹ The dialysis machine delivers dialysis fluid with the intended flow rate, temperature, and chemical composition. The dialysis machine has monitoring and safety systems for air, blood, conductivity, and pressure; blood and dialysate pumps; a heating system; a dialysate mixing and degassing unit; and an ultrafiltrate balancing system. The role of the water purification system is to produce water for dialysis that complies with set chemical and microbiologic standards.

DIALYZER DESIGNS

The dialyzer provides controllable transfer of solutes and water across the semipermeable membrane. The flows of dialysate and blood are separated and countercurrent. The dialyzer has four ports, one inlet and one outlet port each for blood and dialysate. The semipermeable dialysis membrane separates the blood compartment and the dialysate compartment. The transport processes across the membrane are diffusion (dialysis) and convection (ultrafiltration). The removal of small solutes occurs primarily by diffusion; larger components, such as β_2 -microglobulin, are more effectively removed by convection. The hollow-fiber dialyzer is currently the most effective design; it delivers high dialysis efficiency with low resistance to flow in a small device.

DIALYSIS MEMBRANES

Membranes vary with respect to chemical structure, biophysical properties such as transport characteristics, and biocompatibility (Fig. 89.1).

Materials

The original widely used membrane material was cellulose, which is made up of repetitive polysaccharide units containing hydroxyl groups. In cellulose acetate, 80% of the hydroxyl groups are replaced by acetate radicals. Synthetic tertiary amino compounds are added during cellulose membrane synthesis to form cellulosynthetic membranes. More recent membranes are not cellulose based but instead are built of entirely synthetic materials, such as polyacrylonitrile, polysulfone, polycarbonate, polyamide, and polymethylmethacrylate. These synthetic membranes provide superior biocompatibility and are widely used.

Transport Properties

Transport of molecules across the dialysis membrane is due to (1) the concentration gradient (diffusive transport) and (2) the hydrostatic pressure gradient across the membrane (convective transport) and is dependent on membrane pore size. Dialyzer efficiency in terms of urea removal depends on the surface area (usually 0.8 to 2.1 m²). High-efficiency dialyzers have a high surface area irrespective of pore size and possess a superior clearance for small molecules but may have small pores and thus a low ability to remove large molecules such as β_2 -microglobulin. The dialyzer mass transfer area coefficient (K_oA) for urea is a measure of the theoretically maximal possible urea clearance (ml/min) at infinite blood and dialysate flow rates. Dialyzer efficiency can be categorized according to K_oA for urea as low (<500 ml/min), moderate (500 to 700 ml/min), and high (>700 ml/min). In contrast to the dialyzer clearance of a substance, its K_oA is independent of the flows in the blood and in the dialysate compartment. High-flux dialyzers have pores large enough to allow the passage of larger molecules such as β_2 -microglobulin (M_r 11,800 d). Water permeability is described by the ultrafiltration coefficient (K_{uf} , in ml transmembrane ultrafiltration/h/mm Hg transmembrane pressure). K_{uf} is high in high-flux dialyzers, with ultrafiltration coefficients up to 80 ml/h/mm Hg. During high-flux HD, backfiltration (the flow of dialysate into the blood due to higher hydrostatic pressure on the dialysate side) may result in a transfer of 5 to 10 liters of dialysate into the blood. Therefore, water quality is of paramount importance when high-flux dialyzers are used.

In the recent prospective, randomized Membrane Permeability Outcome (MPO) study, a survival benefit of high-flux membranes was seen among patients with serum albumin levels of 4 g/dl or lower.² This finding contrasts with the HEMO study, which did not show any effect in patients with hypoalbuminemia but did show survival benefit in patients on dialysis for more than 3.7 years before the trial.³ These differences may be related in

Dialysis Membrane Properties			
Membrane	Membrane Name (example)	High or Low Flux	Biocompatibility
Cellulose	Cuprophane	Low	Low
Semisynthetic cellulose			
Cellulose diacetate	Cellulose acetate	High and low	Intermediate
Cellulose triacetate	Cellulose triacetate	High	Good
Diethylaminoethyl-substituted cellulose	Hemophane	High	Intermediate
Synthetic polymers			
Polymethylmethacrylate	PMMA	High	Good
Polyacrylonitrile methacrylate copolymer	PAN	High	Good
Polyacrylonitrile methallyl sulfonate copolymer	PAN/AN-69	High	Good
Polyamide	Polyflux	High and low	Good
Polycarbonate/polyether	Gambrane	High	Good
Polyethylene/vinyl alcohol	EVAL	High	Good
Polysulfone	Polysulfone	High and low	Good

part to population characteristics (race, recruitment of incident or prevalent patients) and fluxes achieved.

SAFETY MONITORS

Safety monitors are important integral parts of the dialysis machine. Pressure monitors are in most machines integrated to monitor the system pressure in critical positions¹ (Fig. 89.2):

- Between the arterial side and the blood pump (pre-pump arterial pressure) to assess the suction pressure. Overly negative values may signal reduced arterial inflow and access problems.
- Between the blood pump and the dialyzer inlet (post-pump or dialyzer inflow pressure) to assess the dialyzer inflow pressure. A high pressure may signal dialyzer clotting.
- Between the dialyzer outlet and the air trap (venous pressure) to control the return pressure. A high pressure may point to an obstruction in the venous limb; it is important to consider that in the event of venous needle displacement, the venous pressure will remain positive because of the needle's flow resistance, and no pressure alarm may occur.

A venous air detector and air trap are located downstream of the venous pressure monitor. A positive signal at the air detector automatically clamps the venous line and stops the blood pump. A blood leak detector is placed in the dialysate outflow line. Dialysate temperature is constantly monitored. Dialysate is produced by a proportioning system that mixes acid and bicarbonate concentrates with water. The osmolarity of the dialysate translates into conductivity, which is measured by the dialysis conductivity monitor. The ultrafiltration rate has to be controlled precisely, nowadays in most machines by a volumetric control system.

ANTICOAGULATION

Usually unfractionated or, in some countries, low-molecular-weight (LMW) heparin is used to prevent blood clotting in the

Figure 89.2 Blood circuit for hemodialysis. A, The blood circuit. B, The pressure profile in the blood circuit with an arteriovenous fistula as the vascular access.

extracorporeal circuit. Constant infusion of heparin, repeated bolus of heparin, or single bolus of LMW heparin is used. A number of alternative modalities are available for patients at high risk for bleeding or who have contraindications to heparin, such as saline flushes, regional citrate anticoagulation, prostacyclin, danaparoid, argatroban (direct thrombin inhibitor), and lepirudin (recombinant hirudin). Lepirudin has the disadvantage of very long half-life in dialysis patients. In some institutions, regional citrate anticoagulation is used routinely, especially in patients with recent surgery, coagulopathies, thrombocytopenia, active bleeding, pericarditis, and heparin-associated side effects (such as heparin-induced thrombocytopenia type II, pruritus, rapidly progressive osteoporosis, alopecia). Neutrophil activation may be reduced with regional citrate anticoagulation compared with heparin anticoagulation.

A typical routine prescription of constant infusion heparin is to administer an initial bolus of 2000 IU followed by a heparin infusion (800 to 1200 IU/h) ending 30 to 60 minutes before the end of the session. Applying the repeated bolus method, an initial heparin bolus of, for example, 4000 IU is followed by, for example, 1000 to 2000 IU after 2 hours. Although the half-life of LMW heparin may be prolonged with renal failure, it has proved safe with fewer bleeding episodes, if appropriate dose reductions are made. LMW heparin has become the anticoagulant of choice in many centers in Europe for routine outpatient HD sessions. LMW heparin is given as a bolus at the beginning of the session. Routine monitoring of whole-blood partial thromboplastin time, activated clotting time, or factor Xa (with LMW heparin) is usually not necessary.

DIALYSATE FLUID

Water and Water Treatment

A standard 4-hour HD session exposes the patient to 120 to 160 liters of water. Therefore, water quality is of paramount importance to the patient's well-being. Water for the dialysate may be subjected to filtration, softening, and deionization, but it is ultimately purified in most centers by reverse osmosis. Reverse osmosis entails forcing water through a semipermeable membrane at very high pressure to remove microbiologic contaminants and more than 90% of dissolved ions.

Standards for chemical quality of water are widely accepted, but there is less consensus as to acceptable levels of bacterial and endotoxin contamination.⁴ Municipal water supplies may contain a variety of contaminants that are toxic to HD patients. Substances added to the water, such as aluminum and chloramines, cause significant morbidity. Aluminum accumulation may result in a severe neurologic disorder (speech abnormalities, muscle spasms, seizures, and dementia), bone disease, and erythropoietin-resistant anemia. Plasma aluminum concentration should be monitored regularly; levels should be less than 1 $\mu\text{mol/l}$, and levels above 2 $\mu\text{mol/l}$ should prompt the search for excessive exposure (aluminum-based phosphate binders may be an important source). Chloramines have been associated with hemolysis and methemoglobinemia. Copper and zinc may leach from plumbing components and may cause hemolysis. Lead has been associated with abdominal pain and muscle weakness. Nitrate and nitrite may cause nausea and seizures. High concentrations of calcium may cause the hard water syndrome, characterized by acute hypercalcemia and hypomagnesemia, hemodynamic instability, nausea, vomiting, muscle weakness, and somnolence.

Gram-negative bacteria produce endotoxins (pyrogenic lipopolysaccharides from the outer bacterial cell wall), and fragments of these endotoxins may be responsible for some dialysis-related symptoms. Exposure to bacteria and endotoxin is associated with rigors, hypotension, and fever; even low levels of microbiologic contaminants may contribute to chronic inflammation in HD patients. Bacteria may proliferate in the biofilm, a coating on surfaces consisting of microcolonies of bacteria embedded in an extracellular matrix secreted by the cells, protecting the bacteria from antibiotics and disinfectants. The microbiologic standards for HD water, acid and basic concentrates, dialysis fluid, and online substitution fluid vary between regions (Fig. 89.3).⁴ The harm done by the passage of endotoxin through the dialysis membrane by backfiltration includes stimulation of inflammation, decreased response to erythropoiesis-stimulating agents, and possible aggravation of atherosclerosis. Use of a polysulfone or polyamide filter in the dialysate line may be adequate to remove endotoxins, but smaller molecules including bacterial DNA fragments may pass through the dialyzer and stimulate immune cells. In the absence of routine hot-water disinfection of the machine and the connections to the water loop, the only way that endotoxin concentration can be kept low is by frequent measurement and disinfection when concentration exceeds accepted standards.

Ultrapure water is defined as bacterial count below 0.1 colony-forming unit/ml and endotoxin below 0.03 endotoxin unit/ml and is recommended by both European and American guidelines for use with high-flux dialyzers. Ultrapure water represents a basic prerequisite for dialysis modalities using online production of substitution fluid (online hemofiltration or hemodiafiltration).

Liquid bicarbonate dialysis fluid concentrate distributed in a central system with piping may be a source of bacterial growth. Acid concentrates in canisters and bicarbonate powder represent no bacterial growth risk.

Dialysis Solution

Dialysis fluid can be considered a drug to be adjusted to the individual patient's needs. In modern machines, dialysate is made by mixing two concentrate components, which may be provided as liquid or dry (powder) concentrates. The bicarbonate component contains sodium bicarbonate and sodium chloride; the acid component contains chloride salts of sodium, potassium (if needed), calcium, magnesium, acetate (or citrate), and glucose (optional). These two components are mixed simultaneously with purified water to make the dialysate. Dialysate proportioning pumps ensure proper mixing. The relative amounts of water, bicarbonate, and acid components define the final dialysate composition. Bicarbonate has replaced acetate as the dialysate buffer in most countries. Typical concentrations of dialysate components are given in Figure 89.4. Dialysate containing citrate (0.8 mmol/l) has recently been introduced, which may allow a reduction in heparin dose. Dialysate composition can be further modified by changing the mixing fraction and by adding salt solutions; potential advantages and disadvantages of dialysate modifications are shown in Figure 89.5. Modern machines allow an alteration of the bicarbonate concentration by changing the mixing ratio of water to bicarbonate. A variable sodium option allows the adaptation of the dialysate sodium concentration to the patient's needs. Glucose is usually added to prevent intradialytic hypoglycemia, but glucose concentrations of 200 mg/dl (11 mmol/l) may result in hyperglycemia and hyperinsulinemia.

Glucose	0–11	5.5
	(0–200 mg/dl)	(100 mg/dl)

Figure 89.4 Composition of dialysates for bicarbonate dialysis.

To avoid the need for large volumes of water, spent dialysate can be regenerated by sorbents. These systems may need as little as 6 liters of tap water for a regular dialysis treatment, which makes them particularly attractive for home HD or arid areas.

BIOCOMPATIBILITY

The contact of blood with lines and some types of membranes triggers an inflammatory response akin to that seen in infection. Biocompatibility indicates a membrane that does not produce a

toxic, injurious, or immunologic response on contact with blood. Although many components of the dialysis procedure contribute to the degree of biocompatibility, it is the membrane itself that is most important. Biocompatibility is of particular importance with the use of cellulose membranes, whereas synthetic membranes and reused membranes activate complement to a much lesser extent (see Fig. 89.1). Blood contact with the dialysis membrane activates the complement cascade (most prominent in cellulose membranes), the coagulation cascade, and cellular mechanisms (Fig. 89.6). Activation of complement peaks at 15 minutes after the start of dialysis and lasts up to 90 minutes. Regional citrate anticoagulation may improve biocompatibility by reduced granulocyte degranulation.⁵ Dialyzer reuse with appropriate antibacterial substances is also associated with improved biocompatibility.

HEMOFILTRATION

Hemofiltration (HF; Fig. 89.7) differs markedly from HD in the mechanisms by which the composition of the blood is modified. In the simplest form of HF, blood under pressure passes down one side of a highly permeable membrane, allowing both water and substances up to about 20 kd to pass across the membrane by convective flow, depending on the membrane and its permeability. During HF, the filtrate is discarded and the patient receives a substitution fluid either before (predilution) or after (postdilution) the dialyzer. The substitution fluid contains the major crystalloid components of the plasma at physiologic levels. Both bicarbonate and lactate are used as buffers. The rate of fluid removal and substitution fluid infusion can be adapted to the patient's need. HF is particularly useful as a continuous renal replacement therapy in an intensive care setting.⁶

Advantages and Disadvantages of Modifications of Dialysate Composition		
Component	Advantage	Disadvantage
Sodium	Increased Hemodynamic stability	Thirst; intradialytic weight gain; high blood pressure; sodium toxicity?
	Decreased Reduced osmotic stress in the presence of predialytic hyponatremia	Intradialytic hemodynamic instability
Potassium	Increased Fewer arrhythmias in digoxin intoxication with hypokalemia; may improve hemodynamic stability	Hyperkalemia
	Decreased Increased dietary potassium intake	Arrhythmias; risk of sudden death
Calcium	Increased Suppresses PTH, increased hemodynamic stability	Hypercalcemia, vascular calcification, adynamic bone disease due to PTH suppression
	Decreased Permits more liberal use of calcium containing phosphate binders	Stimulation of PTH, reduced hemodynamic stability
Bicarbonate	Increased Acidosis control improved	Postdialytic alkalosis; increased mortality
	Decreased No postdialytic alkalosis	Promotes acidosis; increased mortality
Magnesium	Increased Hemodynamic stability, less arrhythmias, suppresses PTH	Altered nerve conduction, pruritus, renal bone disease
	Decreased Permits use of magnesium containing phosphate binders; improved bone mineralization; less bone pain	Arrhythmias, muscle weakness and cramps, elevated PTH
Glucose	Decreased Avoidance of intradialytic hyperglycemia and hyperinsulinemia	Increased risk of disequilibrium (rare), hypoglycemia
	Increased Lower risk of disequilibrium	Intradialytic hyperglycemia and hyperinsulinism
Citrate	Heparin-sparing effect	High blood citrate levels in liver failure

HEMODIAFILTRATION

Hemodiafiltration (HDF; Fig. 89.8) combines the benefits of HD (high transport rate of low-molecular-weight solutes by diffusion) and HF (high convective transport of substances). HDF is used as both a continuous and an intermittent renal replacement therapy. HDF offers potential benefits regarding anemia correction, inflammation, oxidative stress, lipid profiles, and calcium-phosphate product.⁷ Higher costs and, in some countries, the decisions of regulatory boards concerning fluid infusion prevent the widespread use of HDF, despite its likely benefits over conventional HD. Randomized controlled trials of HD and HDF will determine its true value.

DIALYSIS TIMES

HD has conventionally been delivered in three treatment sessions per week. This developed as a practical compromise between the physiologic benefits of replacing renal function by HD (“the more the better”) and the practicalities of delivering HD in terms of both the patient’s tolerability and the facility’s organization. There is good evidence that twice-weekly HD provides inferior outcomes to three times weekly, except in occasional patients with substantial residual renal function. Treatment times of 3 to 4 hours per session are now typical, but a few centers have maintained the longer hours (up to 8 hours per session) that were originally necessary because of the relative inefficiency of the available HD techniques. It remains controversial whether the excellent long-term outcomes of patients receiving prolonged HD are related to selection bias rather than real advantages. If longer hours of HD were of proven benefit,

this would provide major planning challenges to HD units organized around three times weekly shorter HD and might renew interest in nocturnal HD either in the home or in treatment facilities.

Two large trials organized by the Frequent Hemodialysis Network (FHN) are currently under way to investigate the effect of increased HD frequency on outcomes.⁸ Primary endpoints are changes in left ventricular mass as measured by magnetic resonance imaging and quality of life, including cognitive measures. One FHN randomized trial is comparing in-center six times per week short daily HD versus conventional three times per week in-center HD. The other is comparing nocturnal home HD with conventional in-center HD. The results of these trials may become available in 2010.

ADDITIONAL DEVICES AND TECHNOLOGIES

Blood Volume Monitoring

A decrease in blood volume due to ultrafiltration is one of the main causes of intradialytic hypotension. Blood volume monitors provide continuous noninvasive monitoring of relative changes in blood volume by continuous measurement of plasma protein concentration by ultrasound or of hematocrit by optical scattering. Too rapid changes in blood volume from baseline indicate decreased plasma refilling rates and may precede intradialytic hypotension. Blood volume monitoring can be particularly useful for monitoring of hemodynamically unstable dialysis patients. Because blood volume is only loosely related to the volume of the extracellular fluid, monitoring of relative blood volume is of no help in determining dry weight.⁹ In some dialysis machines,

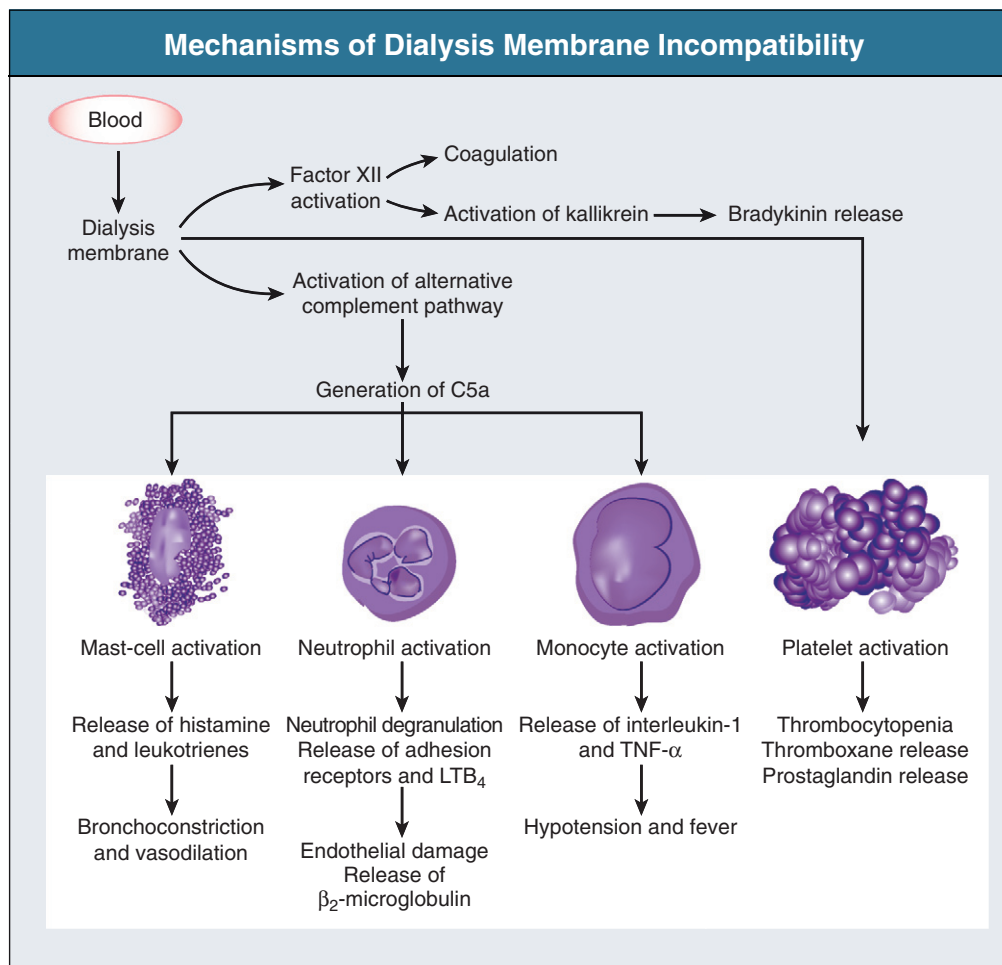

Figure 89.6 Mechanisms of dialysis membrane incompatibility. Pathways involved in the body's response to dialysis membranes. LTB₄, leukotriene B₄; TNF-α, tumor necrosis factor α.

Figure 89.7 The principle of hemofiltration. Substitution fluid is usually given either pre- or postdilution, but not both.

Figure 89.8 The principle of hemodiafiltration. Substitution fluid is usually given either pre- or postdilution, but not both.

blood volume monitor signals are used to automatically adjust ultrafiltration rates. This approach has been shown to reduce the frequency of symptomatic intradialytic hypotension.¹⁰

Ultrafiltration Profiling

The ultrafiltration rate is usually kept constant but can be changed during the dialysis session in a preprogrammed manner (ultrafiltration profiling). It may be advantageous to remove a large proportion (e.g., two thirds) of the ultrafiltration volume in the first half of the HD session. Because of a high initial plasma refilling rate, severely overhydrated patients may tolerate a higher ultrafiltration rate in the early stages, and dry weight may be reached more easily. In some machines, predefined ultrafiltration profiles are incorporated, for example, triangular ultrafiltration ramps and exponential profiles; in most instances, the ultrafiltration rate is initially high and then turned down. The clinical benefits of ultrafiltration profiling are under debate; in the absence of clear evidence-based recommendations, we suggest that ultrafiltration profiling be considered in patients prone to intradialytic complications, such as hypotensive episodes.

Sodium Profiling

The dialysate sodium concentration is normally kept constant throughout the dialysis treatment. The variable sodium option allows dynamic changes of the dialysate sodium concentration during the treatment (sodium profiling). Although high-grade evidence is lacking, patients with hemodynamic instability may benefit from sodium profiling in which the initial sodium concentration is kept high and then slowly reduced by a degree similar to the initial sodium rise. Otherwise, sodium profiling usually results in a sodium load to the patient in the absence of equivalent reductions in dialysate sodium concentrations that may result in thirst and consequent increased interdialytic weight gain.

Online Clearance Monitoring

Sodium and urea clearances are identical for practical purposes. Because the conductivity of the dialysate is largely a function of the dialysate sodium concentration, online clearance monitors can use this feature to compute the urea clearance (K) of a dialyzer. Changes in inflow dialysate sodium concentration are related to the respective changes of conductivity in the dialysate outflow. The conductivity clearance is equivalent to urea clearance, and Kt is easily calculated. Together with estimates of V (total body water), Kt/V can be determined with each treatment.

Blood Temperature Monitoring

During standard HD, the core temperature usually increases. Because the thermoregulatory response to rising core temperature (dilation of thermoregulatory vessels) may offset the vascular response to hypovolemia (vasoconstriction), this increase in internal heat production might be in part responsible for the intradialytic hemodynamic instability. Reducing dialysate temperature to a level of 0.5°C below core temperature is in general safe. “Cool” dialysate has been shown to improve vascular stability during dialysis. The core temperature can be controlled by the blood temperature monitor, which adapts the dialysate

temperature according to the desired core temperature. A meta-analysis of 22 studies concluded that intradialytic hypotension occurred 7.1 times less frequently with cool dialysis¹¹ without reduction in urea clearance. When no blood temperature monitor is available, the dialysate temperature can be set initially to the patient's core temperature. If this is well tolerated and intradialytic hypotension still occurs, the dialysate temperature may be reduced up to 0.5°C below the patient's core temperature, unless cold discomfort occurs.

Hemodiafiltration

High-volume HDF (removal and replacement of up to 50 liters per treatment) is in common use in parts of Europe and Asia. The beneficial effects are controversial, but a study suggests favorable short-term outcomes. A large trial of 800 chronic HD patients randomized between online HDF and low-flux HD observed for 3 years is under way with all-cause mortality as the primary endpoint.¹²

Sorbents, Nanotechnology, Wearable Artificial Kidney

Use of sorbents to absorb nondialyzable molecules will test the relevance as uremic toxins of the many protein-derived substances that accumulate in the plasma of uremic patients. Nanotechnological approaches to dialysis therapy are under intensive investigation.¹³ A study has reported the successful short-term use of a wearable artificial kidney.¹⁴

Hemodialysis: Outcomes and Adequacy

Martin K. Kuhlmann, Peter Kotanko, Nathan W. Levin

From an idealistic clinical perspective, an adequately treated hemodialysis (HD) patient is physically active, well nourished, nonanemic, and nonhypertensive with a maintained quality of life and a life expectancy that is not inferior to that of healthy subjects. Despite these idealistic goals, outcomes for dialysis patients expressed in terms of mortality, hospitalization, and quality of life regrettably remain comparable to those observed in patients with solid organ cancer. The mean life expectancy of an average 60-year-old HD patient currently can be estimated between 5 and 7 years, with an annual mortality rate between 13% and 20% (www.usrds.org). Mortality in HD patients differs by gender and race; in the United States, there is lower mortality in African Americans compared with Caucasians, in Hispanics compared with non-Hispanics, and in Asians compared with any other racial group. Data from the Dialysis Outcomes and Practice Pattern Study (DOPPS) suggest that variations in practice patterns, such as prescribed dialysis treatment time, average epoetin dose, preferred vascular access type, and number of patients with central venous catheters, may account for some of these differences. Outcomes are also directly related to comorbid factors occurring during evolution of chronic kidney disease (CKD), such as atherosclerotic vascular disease, diabetes, and arterial hypertension, and to background cardiovascular mortality of the respective general population.¹ Indeed, the majority of CKD patients die mainly of cardiovascular causes before reaching end-stage renal disease (ESRD). Besides cardiovascular disease (discussed further in Chapter 78), other major factors influencing outcome that are common to all patients with ESRD include anemia (see Chapter 79) and control of bone and mineral metabolism (see Chapter 81).

In this chapter, we discuss dialysis-related factors influencing outcome in patients receiving maintenance HD (see summary in Fig. 90.1). A key factor influencing outcome is “adequacy” of dialysis, a term originally used exclusively to describe dialysis dosing measured by small solute removal. However, dialysis adequacy now has a broader meaning encompassing all aspects of the replacement of excretory and endocrine functions of the kidney that affect outcome.

Unfortunately, randomized, controlled trials are few in HD, and lower grades of evidence support the published clinical practice guidelines, which are listed in Figure 90.2.

ADEQUACY OF DIALYSIS DOSE

Uremic Toxins

The retention in the body of compounds that normally are metabolized or secreted into the urine by healthy kidneys results in the

uremic syndrome. These compounds are called uremic retention solutes or uremic toxins when they interact negatively with biologic functions. Uremic toxins include a small group of inorganic compounds, such as water, potassium, phosphate, and trace elements, and a much larger group of organic compounds that are further subdivided into small water-soluble solutes (<500 d), middle molecules (>500 d), and protein-bound solutes (Fig. 90.3). A continuously updated list of uremic toxins is provided at <http://www.uremic-toxins.org/>. The catalogue of uremic toxins is long, but only a few compounds have been associated with outcomes. Mortality has repeatedly been shown to be associated with the clearance of urea. Of commonly measured protein-derived substances, only the serum concentration of β_2 -microglobulin correlates with mortality. Recently, a higher free concentration of the protein-bound solute *p*-cresol has also been reported to be associated with mortality.² Uremic toxicity is more than the retention of urea or water-soluble compounds alone, but current dialysis and dialysis-related treatments do not remove any significant quantity of substances larger than 10 to 15 kd. Future means of removing higher molecular weight toxins or protein-bound substances may include the use of sorbents in addition to traditional diffusive and convective dialysis strategies.

Urea as a Surrogate Marker of Uremic Toxicity

Among all potential uremic toxins, only urea, a 60-dalton small water-soluble compound, is established as a classic marker of uremic solute retention and removal. Urea, which itself shows little toxicity, is a metabolite of amino acid metabolism; urea generation therefore depends on protein intake and the balance between protein anabolism and catabolism. The removal of urea was originally considered to be representative for the removal of other water-soluble solutes with a higher pathogenic impact, although it is now clear that urea removal does not closely parallel that of other small water-soluble compounds, protein-bound solutes, or middle molecules.³ Nevertheless, adequacy of HD dosing remains conventionally evaluated by removal of urea.

Assessment of Dialysis Dose

Adequacy in terms of dialysis dose refers to delivery of a treatment dose that is considered sufficient to promote an optimal long-term outcome. The delivered dose of dialysis is assessed by the removal of urea and expressed either by the urea reduction ratio or by the treatment index Kt/V . Simply following predialysis blood urea nitrogen (BUN) or serum urea is insufficient; low serum urea may much more reflect malnutrition due to inadequate protein intake rather than adequate dialysis urea removal.

Factors Related to Dialysis Outcomes			
Factor	Effects of Dialysis	Effect on Dialysis	Effect on Outcome
Patient Characteristics			
Age		Hemodynamic instability	Profound increase in CV disease
Gender		Intensified therapy in case of pregnancy	Possible interaction with increased dialysis dose
Race/Ethnicity			Definite effects on cardiac outcomes esp. atherosclerosis
Body size (BMI)		Requires longer Tx-time	Small people worse outcomes
Comorbidities			
Diabetes mellitus	Worse metabolic control; falsely low Hb _{A1C}	Autonomic dysfunction→ ↑ IDWG	Increased mortality due to CVD; increased risk of calciphylaxis
Arterial hypertension	Increase or decrease	low BP→↑ dialysis time; high BP→↓ dry weight	Both low and high blood pressure associated with ↑ mortality
Cardiomyopathy	May be worsened	Makes UF difficult	Associated with poorer survival
Depression	Dialysis dose; organizational issues	Missed treatments	Increased morbidity, reduced QoL
Transplant eligibility	May be improved by dialysis adequacy	Incompliance	
		Use of HDF in non-eligible patients	Lower mortality in patients on waiting list
Anemia			
Hemoglobin (Hb)	Rises during ultrafiltration	High Hb may limit phosphate elimination	Low Hb associated with LVH
Epo resistance	May be improved by adequate dialysis dose	Switch from catheter to fistula	High Hb associated with access thrombosis and mortality
Epo variability			Association with poor survival
			Possibly associated with poor outcomes
Mineral and Bone Disease			
PTH	↑ with low dialysate Ca ⁺⁺ ↓ with high dialysate Ca ⁺⁺	Hypocalcemia→vascular instability	↑PTH possibly related to morbidity and mortality
Vitamin D		Hypocalcemia→vascular instability	Associated with osteomalacia
			Vit D use associated with increased survival
Hyperphosphatemia	Affected by dialysis time and frequency		Increased morbidity and mortality,
Nutrition/Inflammation			
Inflammation	Induced by dialysate impurities and bioincompatibility	Choice of access	Increased morbidity and mortality induces Epo resistance
Protein-energy malnutrition	Affected by dialysis dose, membrane flux	Volume control poorer	Increased morbidity and mortality
Low serum albumin	Induced by dialysate impurities	May limit refilling of plasma volume	Risk of IDH, increased morbidity and mortality
Overhydration	Increased with positive sodium balance	Easier dialysis due to rapid plasma refilling	Increased morbidity and mortality
Central venous catheter		Reduced dialysis dose due to low QB, thrombosis and infection	Increased BP and LVH
Beta-2 microglobulin	↓ with high flux dialyzers		Increased mortality, Epo resistance, inflammation
			High plasma concentration associated with mortality

Figure 90.1 Factors related to dialysis outcome. BMI, body mass index; BP, blood pressure; CVD, cardiovascular disease; EPO, erythropoietin; HDF, hemodiafiltration; IDH, intradialytic hypotension; IDWG, interdialytic weight gain; LVH, left ventricular hypertrophy; PTH, parathyroid hormone; Qb, blood flow rate; QoL, quality of life; Tx, treatment; UF, ultrafiltration.

If urea removal is inadequate, then dialysis is inadequate, regardless of the serum urea level.

Intradialytic Urea Kinetics

Dialyzers are highly efficient in removal of urea from the blood, reducing the urea concentration during one passage by 80% to 90%. Intradialytic serum urea kinetics were originally described by single-compartment (single-pool) models, assuming that full equilibration between blood and tissue compartments occurs immediately and without time delay. In such models, the change in BUN follows first-order kinetics, with a linear decline and no urea rebound (Fig. 90.4, *dashed line*). *In vivo*,

however, intercompartmental urea redistribution is delayed, and the intradialytic urea concentration in the blood compartment is always lower than in the tissue compartments. Full equilibration between blood and tissue compartments is only completed by 30 to 60 minutes after dialysis. These features of urea kinetics are more accurately described by double-pool models that take into account delayed intercompartmental urea redistribution and postdialysis urea rebound (Fig. 90.4, *solid line*).

Current methods for assessment of dialysis dose are based on the predialysis and postdialysis difference in BUN and include the urea reduction ratio (URR), the single-pool Kt/V ($spKt/V$), the equilibrated Kt/V (eKt/V), and the weekly standard Kt/V ($std-Kt/V$).

Urea Reduction Ratio

URR refers to the treatment-related reduction of serum urea concentration and is computed as follows:

$$\text{URR (\%)} = (1 - C_t/C_0) \times 100\%$$

where C_t is postdialysis and C_0 is predialysis serum urea concentration.

URR is a simple but rather imprecise way to quantify dialysis dose because it does not take into account intradialytic urea generation and convective urea removal by ultrafiltration. Despite these limitations, URR correlates well with dialysis outcome and is an accepted method for assessment of dialysis adequacy. A minimum URR of 65% to 70% is recommended for adequate HD.

Treatment Index Kt/V

The treatment index Kt/V is the most widely used parameter to assess dialysis dose. Kt/V is a dimensionless number representing volume cleared ($K \times t$, in liters) divided by volume of distribution

(V , in liters). The concept of Kt/V may be applied to any substance but in clinical practice is almost exclusively used for urea, where K is the dialyzer blood water urea clearance (liters per hour), t is dialysis session length (hours), and V is the distribution volume of urea (liters), which equates closely to total body water. A delivered Kt/V of 1.0 implies that the volume of plasma cleared of urea ($K \times t$) during a dialysis session is equal to urea distribution volume (V). Kt/V and URR are mathematically linked by the following equation:

$$Kt/V = -\ln(1 - \text{URR})$$

where \ln represents the natural logarithm.

Accordingly, Kt/V equals 1.0 when URR equals 0.63, or 63% of whole-body urea has been removed. The equation is formally based on a single-pool model and does not take into account intradialytic urea generation and convective urea removal by ultrafiltration. This formula, however, has built the basis for further development of $spKt/V$ and eKt/V equations.

Single-Pool Kt/V ($spKt/V$)

Daugirdas⁴ has adjusted the equation for intradialytic urea generation and for ultrafiltration volume. His second-generation formula is validated for a Kt/V range between 0.8 and 2.0 and is widely used because of its simplicity and accuracy.

$$spKt/V = -\ln(R - 0.008 \times t) + (4 - 3.5 \times R) \times UF/W$$

where \ln is the natural logarithm, R is the postdialysis/predialysis serum urea ratio, t is the treatment time (hours), UF is ultrafiltration volume (liters), and W is the patient's postdialysis body weight (kilograms).

Accurate computation of $spKt/V$ requires a nonequilibrated post-HD serum urea concentration and accurate timing of blood collections. Pre-HD blood samples must be collected right at the start of the treatment and post-HD samples immediately after termination of dialysis, at the beginning of urea rebound. The nonequilibrated post-HD serum urea concentration is always lower than the equilibrated value, and thus nonequilibrated URR and Kt/V values are always higher than the respective equilibrated values.

Equilibrated Kt/V (eKt/V)

Dialysis dose is more accurately estimated by eKt/V based on the equilibrated postdialysis serum urea concentration. The amount of urea rebound depends on the intensity of dialysis: the shorter and more intense a treatment, the higher the urea rebound. Rebound can be predicted from nonequilibrated postdialysis serum urea concentration and the intensity of the dialysis treatment expressed as the number of Kt/V units per hour (Kt/V per time unit = K/V):

$$eKt/V = spKt/V - (0.6 \times spKt/V) - 0.03 \text{ (arterial access)}$$

The *arterial* access equation is valid only for dialysis treatments using arterial access, such as arteriovenous fistulas or grafts. For treatments using central venous catheters, in which cardiopulmonary recirculation is less and rebound therefore lower, the following *venous* access equation should be applied:

$$eKt/V = spKt/V - (0.47 \times spKt/V) - 0.02 \text{ (venous access)}$$

From these equations, it is clear that eKt/V is always lower than $spKt/V$. With a conventional 4-hour HD treatment, eKt/V is about 0.2 Kt/V units lower than $spKt/V$. The difference is even larger with short, high-efficiency HD or hemodiafiltration, in which urea rebound is higher. Typical results of $spKt/V$ and eKt/V for identical treatment characteristics are shown in Figure 90.5.

Single-pool Kt/V or, even better, eKt/V should be assessed monthly, and dialysis prescription should be adapted accordingly. In large cross-sectional studies, mortality increases when $spKt/V$ falls below 1.2, and international guidelines (e.g., KDOQI) recommend a target $spKt/V$ of 1.3 for a conventional dialysis schedule of three times per week.

Weekly Standard Kt/V ($std-Kt/V$)

The weekly dialysis dose is not equivalent to the product of session Kt/V and the number of treatments per week because the total urea mass removed per time unit decreases with increasing dialysis treatment time and dose as a result of lowering of serum urea concentration over time. This is exemplified by looking at a doubling of Kt/V from 1.0 to 2.0, when the total mass of urea removed is not doubled but only increased by about 24% (Fig. 90.6). With the weekly $std-Kt/V$ concept, the *intermittently* provided dialysis urea clearance during 1 week is converted to an equivalent *continuous* “extracorporeal” urea clearance (ml/min), then multiplied by 10,080 (minutes per week) and divided by

Computation of Dialysis Dose: Results Derived from Different Model Equations		
Formula	Result	Comment
$URR = (1 - C_t / C_0) \times 100\%$	67%	Urea rebound, urea generation, and ultrafiltration not taken into account
$Kt/V = \ln(C_0 / C_t)$	1.10	Urea rebound, urea generation, and ultrafiltration not taken into account
$spKt/V = -\ln(R - 0.008 \times t) + (4 - 3.5 R) \times UF/W$	1.33	Single-pool model; urea rebound not taken into account
$eKt/V = spKt/V - 0.6 \times spKt/V/t + 0.03$	1.16	Double-pool model for arteriovenous access including urea rebound
$eKt/V = spKt/V - 0.47 \times spKt/V/t + 0.02$	1.20	Double-pool model for central venous access including urea rebound

Calculations based on dialysis duration (t) = 4 hours; predialysis BUN (C_0) = 90 mg/dl; nonequibrated postdialysis BUN (C_t) = 30 mg/dl; ultrafiltration volume (UF) = 3 liters; postdialysis body weight (W) = 72 kg; $R = C_t/C_0$; URR, urea reduction ratio.

Figure 90.6 Total body urea fraction removed in relation to Kt/V . In this example, 63% of total body urea fraction is removed with Kt/V of 1; doubling of Kt/V to 2 increases the removed urea fraction by an additional 24%.

urea distribution volume V (ml).⁵ The resulting dimensionless $std-Kt/V$ value is directly compatible with peritoneal dialysis weekly Kt/V and with native residual renal Kt/V . Weekly $std-Kt/V$ can be derived graphically by plotting eKt/V of a representative dialysis session onto the respective frequency curve (Fig. 90.7). A maximum $std-Kt/V$ of 2.8/week can be achieved with a conventional thrice-weekly dialysis schedule. To deliver higher $std-Kt/V$, dialysis frequency needs to be increased. Residual renal function expressed as weekly renal Kt/V can simply be added to dialysis $std-Kt/V$.

Independent of the treatment schedule, a minimum target $std-Kt/V$ of 2.0/week including renal Kt/V is recommended for all patients. This is exactly the value that is achieved with a $spKt/V$ of 1.2 given three times per week in an anuric patient.

Figure 90.7 The $std-Kt/V$ concept. The $std-Kt/V$ for any hemodialysis (HD) frequency is derived by plotting eKt/V of a representative dialysis session onto the respective frequency curve. CAPD, continuous ambulatory peritoneal dialysis; CHD, conventional hemodialysis regimen (3x/week); SHD, short daily hemodialysis (6x/week); NHD, nocturnal home hemodialysis (6x/week).

Formal Urea Kinetic Modeling

Formal urea kinetic modeling (UKM) is the most accurate method for assessment of delivered dialysis dose. Besides this, it is the only kinetics-based method for prescription of Kt/V and for measurement of urea distribution volume. UKM has formed the basis for retrospective interpretation of the National Cooperative Dialysis Study and for prescription and control of the HEMO and the Frequent Hemodialysis Network studies. Single-pool Kt/V is modeled from the prescribed dialyzer clearance (K), derived from the intrinsic dialyzer overall transport coefficient K_oA (for details, see Chapter 89), and from prescribed blood and dialysate flow rates, targeted ultrafiltration volume, prescribed treatment time, interdialytic urea generation rate, and assumed urea distribution volume. By comparing modeled Kt/V to delivered Kt/V , the accuracy of delivery of dialysis dose can be assessed.

UKM also accounts for ultrafiltration, intradialytic urea generation, and unconventional dialysis frequencies. Additional benefits of formal UKM in addition to $spKt/V$, eKt/V , and $std-Kt/V$ include the estimation of the normalized protein nitrogen appearance, a marker of spontaneous dietary protein intake, and regular assessment of urea distribution volume. Because of its mathematical complexity, UKM requires advanced computer support. UKM is the most rigorous available method for prescribing and evaluating dialysis dose and is widely used in the United States.

Prescription of Dialysis Dose

Delivered dialysis dose depends on dialysate and blood flow rates, dialyzer efficiency (K_oA), session length (t), and the distribution volume (V) of the uremic toxin studied. For urea, this is total body water volume; but for other small-molecular-weight compounds, V may be substantially different. A standard dialysis prescription should include a minimum treatment time of 4 hours, a blood flow rate of at least 250 ml/min, and a dialysate flow rate of 500 to 800 ml/min. In a new dialysis patient, V is

unknown and has to be estimated (men, 58% of body weight; women, 55% of body weight).

Example

Male, body weight: 76 kg; $V = 58\%$ of body weight = 44 liters
 Target blood flow rate: 300 ml/min; dialyzer efficiency: 80%;
 effective dialyzer urea clearance (K_d) = 240 ml/min; target
 $spKt/V = 1.3$

Required treatment time (min): $1.3 \times V \text{ (ml)} / K_d \text{ (ml/min)} = 238 \text{ min}$

Once dialysis is delivered and Kt/V has been measured, the prescription is adjusted to meet the Kt/V target. In severe and long-standing uremia, the target dose is approached slowly during the course of several sessions to avoid the dialysis disequilibrium syndrome.

Is V the Adequate Denominator for $K \times t$?

Several studies have suggested that patients with small urea V , typically women, tend to do poorly relative to larger people. Because total body water is much more closely related to muscle mass than to body weight, small urea V is a good indicator for low muscle mass. Interestingly, in the HEMO study, a beneficial effect of higher Kt/V was reported for women but not for men.⁴ This implies that individuals with low muscle mass may require a higher clearance in relation to V and therefore raises the question of whether V is the appropriate denominator for dialysis dose. Native renal clearances, in contrast, are commonly related to body surface area (BSA), not to total body water. By analogy, it has been proposed to relate dialysis clearances to BSA. The ratio of BSA to urea V is generally higher in women than in men and decreases with an increment in V . Prescribing dialysis dose in relation to BSA ($K \times t/BSA$) would result in more dialysis for smaller patients of either gender and for women of any size. A nomogram approach for a BSA-adjusted target $spKt/V$ has been published recently.⁶ Although this new approach has not yet been fully validated, it may be recommended for subpopulations with low muscle mass and associated high mortality risk.

Factors Affecting Delivered Kt/V

The effective dialyzer urea clearance K_d depends on blood and dialysate flow rates, dialyzer K_oA , effective dialyzer surface area, hematocrit, anticoagulation, and recirculation. Treatment time t is important for reaching the Kt/V target. Effective treatment time can be substantially shorter than prescribed treatment time because of intermittent pump stops or patient demand. V does not substantially change during a single HD session but may change over time. Dialysis dose needs to be adjusted for an increase in V . On the contrary, if there is a loss in body mass, which is associated with a decrease in V , Kt/V should not be reduced but rather adjusted to the higher, ideal patient V or, as pointed out before, to BSA.

Confronted with an inadequate delivered Kt/V , it is sensible to check whether the studied session was representative of an average session because unusual problems may have occurred (e.g., shortened time, single-needle HD). A frequent cause of low Kt/V is a vascular access problem leading to recirculation. Blood sampling errors should be considered because delayed post-HD sampling will reduce Kt/V . Blood sampling procedures should be standardized in each center (for recommendations, see KDOQI guidelines). If, despite these checks, a low Kt/V remains unexplained, treatment time should be increased to 4.5 or 5 hours.

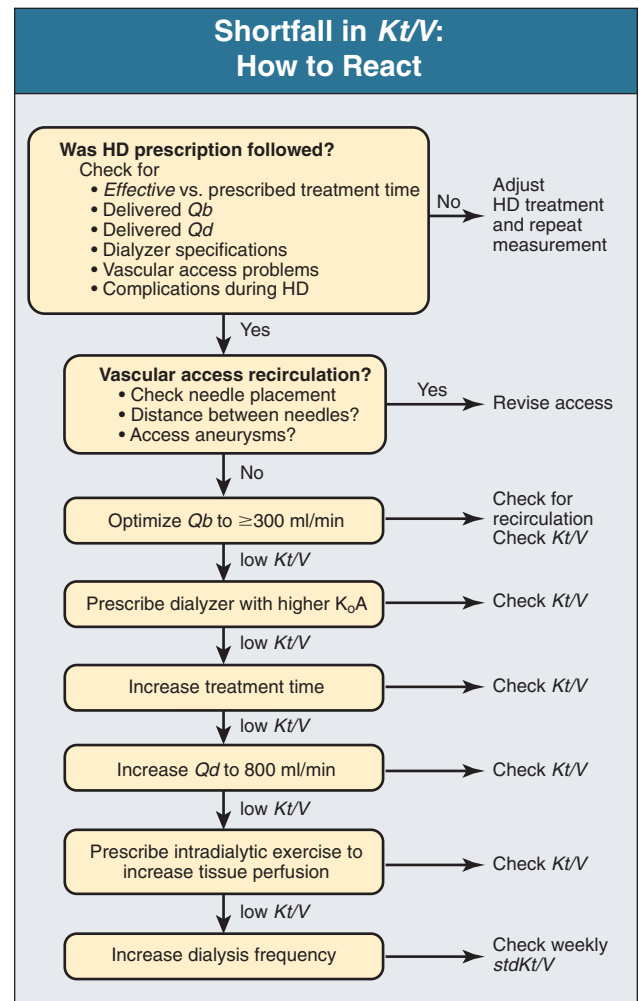

Figure 90.8 Management of low Kt/V . HD, hemodialysis; K_oA , the dialyzer urea mass transfer area coefficient; Q_b , blood flow rate; Q_d , dialysate flow rate.

Prescription of a more efficient dialyzer and higher blood and dialysate flow rates should also be considered (Fig. 90.8). Muscle exercise before or during dialysis improves Kt/V by increasing blood supply to poorly perfused urea rich muscle tissue and thus facilitates urea equilibration. Delivered Kt/V should be checked whenever the dialysis prescription has been modified substantially. Online clearance monitoring allows assessment of Kt/V during each single session without blood sampling.

Recommendations for Dialysis Dose Adequacy

Current recommendations in the United States are as follows:

- A minimum $spKt/V$ of at least 1.2 for both adult and pediatric HD patients. When URR is used, the delivered dose should be equivalent to a Kt/V of 1.2, that is, an average URR of 65%.
- To prevent the delivered dose of HD from falling below the recommended minimum dose, the prescribed dose of HD should be $spKt/V$ 1.3, which corresponds to an average URR of 70%.
- The delivered dose of HD should be measured at least once per month in all adult and pediatric HD patients.

Details on these and other recommendations can be found at the various Web sites listed in Figure 90.2.⁷

OTHER DIALYSIS FACTORS RELATED TO OUTCOMES

Middle Molecule Removal

It is widely held that retention solutes of middle molecular size may play an important role in the pathogenesis of the uremic state and contribute significantly to the high mortality of dialysis patients. Because of higher membrane porosity, high-flux dialyzers have the capacity to remove larger amounts of middle molecules than low-flux dialyzers do, and this may even be further increased by the use of convective dialysis strategies, such as hemodiafiltration. Serum β_2 -microglobulin, a surrogate for other uremic middle molecules, is more effectively removed by high-flux than by low-flux dialysis, and predialysis β_2 -microglobulin levels were found to be related to mortality in patients treated randomly with high-flux or low-flux dialyzers.⁸ Certain subgroups of dialysis patients, such as diabetics, prevalent patients on dialysis for longer than 3.7 years, and incident patients with serum albumin levels below 40 g/l, may benefit most from high-flux dialysis.^{9,10} The European Best Practice Guidelines have recommended maximizing the removal of middle molecules in all dialysis patients.¹¹

Phosphate Removal

Hyperphosphatemia is a major problem in HD (see Chapter 81).¹² Management of hyperphosphatemia is based on phosphate removal by dialysis, dietary phosphate restriction, and intestinal phosphate binding with use of phosphate binder medication. Intradialytic phosphate kinetics differ significantly from urea kinetics, with serum phosphate levels steeply falling during the first 90 to 120 minutes into dialysis and stabilizing thereafter (Fig. 90.9). The intradialytic plateau is explained by phosphate mobilization from various compartments at a rate similar to that of dialyzer phosphate removal. Phosphate removal can be improved by high-flux HD and hemodiafiltration, by the use of larger dialyzer surface area, and, most dramatically, by higher frequency dialysis schedules, such as short daily or daily nocturnal HD. Long frequent dialysis schedules may result in hypo-

phosphatemia so that phosphate has to be added to the dialysate. Target predialysis phosphate levels should be in the normal range.

Preservation of Residual Renal Function

Most patients starting dialysis still have considerable residual renal function (RRF); but by the end of the first year, the majority have lost RRF completely. Only 10% to 20% of patients still have RRF after more than 3 years of dialysis. RRF of 2 to 3 ml/min urea clearance contributes significantly to the elimination of uremic toxins.¹³ This translates into lower serum β_2 -microglobulin, phosphate, potassium, urea, creatinine, and uric acid levels; higher hemoglobin concentration; enhanced nutritional status; better quality of life scores; and a reduced need for dietary and fluid restrictions. Loss of RRF, in contrast, is associated with left ventricular hypertrophy. To assess the relative contribution of RRF to total delivered dialysis dose, weekly dialysis dose should be expressed as *std-Kt/V*. For a patient with an estimated total body water of 40 liters, a residual urea clearance of 2 to 3 ml/min is equivalent to a *std-Kt/V* of 0.5 to 0.75/week. Risk factors for the loss of RRF include activation of the immune system by bioincompatible membranes and dialysate water impurities; intradialytic hypotension; use of angiotensin-converting enzyme inhibitors or nephrotoxic agents, such as radiocontrast media, aminoglycosides, and nonsteroidal anti-inflammatory drugs; and hypercalcemia. Loss of RRF may be delayed by the use of calcium antagonists and adequate target post-HD weight prescription.

Dialysate Composition

Dialysate composition may have a strong long-term impact on outcome. During a standard treatment session, a patient's blood is exposed to 120 to 200 liters of dialysate. The several ingredients of dialysate should therefore be prescribed with great care.

Sodium

Sodium retention is a typical feature of ESRD and an important factor in the pathogenesis of hypertension in HD patients. Judicious control of sodium balance is effective in normalizing blood pressure, and dietary sodium intake should be restricted to 6 g salt or 100 mmol sodium per day. Sodium is mainly removed through ultrafiltration; but depending on the ratio of dialysate to plasma water sodium concentration, it will be additionally removed or delivered to the patient by diffusion. To avoid a positive sodium balance, dialysate sodium should not exceed the patient's average predialysis serum sodium concentration by more than 2 or 3 mmol/l.

Potassium

Potassium removal during dialysis should ideally be equal to the amount accumulated during the interdialytic period. The dialysate potassium concentration has to be set at a level that avoids pre-HD hyperkalemia as well as intradialytic hypokalemia, which may provoke dialysis-induced arrhythmia. The typical dialysate potassium concentration is set between 2.0 and 4.0 mmol/l.

Calcium

In light of the interdialytic positive calcium balance and accelerated vascular calcification as a major cardiovascular risk factor in ESRD, intradialytic calcium delivery to the patient should be

Figure 90.9 Intradialytic kinetics of phosphate removal and mobilization.

avoided. In patients using calcium salts as phosphate binders, a negative intradialytic calcium mass balance is desirable.¹⁴ A standard dialysate calcium concentration of 1.25 to 1.50 mmol/l is recommended by KDIGO. These and higher dialysate calcium concentrations may be associated with tissue calcium accumulation, whereas lower dialysate calcium will stimulate PTH secretion.

Bicarbonate

Chronic metabolic acidosis is associated with decreased protein synthesis and increased protein catabolism and contributes to mineral and bone disorders. Normalized pre-HD bicarbonate levels in the range of 20 to 23 mmol/l are associated with improved survival. Dialysate bicarbonate concentration is typically set between 35 and 40 mmol/l to generate a transmembrane concentration gradient favoring bicarbonate delivery to the patient. Overalkalinization may result in reduced cerebral perfusion.

Treatment Time

Conventional three times a week dialysis remains the standard of care in most countries, where treatment time is typically governed by dialysis dose (Kt/V), with the consequence of longer dialysis in patients with higher urea distribution volumes.

In some countries, such as Germany, a minimum treatment time of 4 hours per HD session is mandatory for demonstration of adequacy. Great care should be given to prescribing and delivering *effective* treatment times, which exclude periods of pump stops or any other interruptions of the treatment session. Even with similar Kt/V , longer treatment times are associated with higher mass removal of urea, creatinine, phosphate, and β_2 -microglobulin compared with shorter treatment times.¹⁵

Weekly treatment time is the one factor with the highest impact on dialysis dosing. More frequent in-center dialysis and longer dialysis hours delivered by in-center or home nocturnal dialysis are increasingly used alternatives to three times weekly treatment. Both modalities offer the opportunity for improved solute clearance and complete removal of interdialytic weight gain with fewer problems because ultrafiltration rates are lower and hypotension is less likely. However, scientific evidence for the extension of weekly treatment time is currently based on only a few small-scale randomized or nonrandomized studies.¹⁶ The results of a larger randomized, controlled study, the Frequent Hemodialysis Network study, are awaited in 2011.

Hydration Status

Overhydration, which is found in the majority of HD patients, is an established risk factor for the development of arterial hypertension, left ventricular hypertrophy, and cardiovascular mortality. It is the goal of an adequate HD treatment to normalize body water homeostasis and extracellular volume to a level comparable with that of subjects of similar age and normal renal function. In clinical practice, this idealized postdialysis body weight is termed dry weight, which may differ substantially from the target weight prescribed by the physician. Because of the difficulties in detecting overhydration of 2 to 3 liters clinically from the presence of edema, high blood pressure, dyspnea, and distended jugular veins, technical methods such as ultrasound (diameter of inferior vena cava), chest radiography, and whole-body bioimpedance should be applied regularly.¹⁷ The prescribed post-HD target weight is achieved by ultrafiltration. High ultrafiltration rates

above 1000 ml/h are associated with an increased risk of intradialytic hypotension, which in turn is associated with an increased long-term mortality risk. Intradialytic hemodynamics are stabilized by isothermic HD, in which the physiologic intradialytic rise in body core temperature, a key factor in the pathogenesis of intradialytic hypotension, is prevented through cooling of the dialysate.¹⁸ In hemodynamically unstable patients, only low ultrafiltration rates and therefore longer dialysis treatment times can accomplish the goal of adequate fluid removal.

Dialysis patients are advised to limit daily fluid intake to 0.5 to 0.75 liter in excess of their average daily diuresis. A positive interdialytic and intradialytic sodium balance is a major factor governing thirst and interdialytic water intake. Dietary salt restriction to 6 g salt per day is recommended to prevent high interdialytic weight gain and the development of arterial hypertension and congestive heart failure.

Dietary Protein and Calorie Intake

HD patients are at risk of malnutrition due to protein-energy wasting, decreased appetite, infection, intercurrent illnesses, hospital admissions, and missed meals after dialysis. The recommended daily intake of 1.0 to 1.2 g protein per kilogram of ideal body weight and 35 kcal per kilogram of ideal body weight is often not met. The nutritional status of dialysis patients should be assessed regularly by clinical and biochemical means, including measurement of protein nitrogen appearance (see Chapter 83).

Vascular Access

The choice of vascular access strongly affects outcome in dialysis patients. A functioning vascular access is a major precondition for adequate dialysis treatment. Native fistulas should always be the first-line vascular access. In cases in which a native fistula cannot be created, a vascular graft may be an alternative. Central venous catheters may be used for bridging until a vascular access can be used for dialysis. Only when a native fistula or a graft is not available may subcutaneous tunneled central venous catheters be used as permanent access. Worldwide, there are large differences in the fraction of patients with central venous catheters used as permanent access. Long-term catheter use is associated with a higher rate of chronic inflammation and acute infection, lower serum albumin levels, impaired response to erythropoietin, and higher hospitalization and mortality rates, mainly due to infection (see Chapter 87). The quality of the vascular access should be assessed regularly by clinical means, such as inspection, palpation, and auscultation, as well as by technical means, including intradialytic measurement of recirculation or access flow rate and Doppler ultrasound technology.

Quality of Life

Quality of life measures may be among the most sensitive indicators of the efficacy of dialysis therapies.¹⁹ Measures of physical and mental aspects of quality of life are recognized to assess the physical and psychological disturbances that can accompany the uremic state and can be modified by renal replacement therapy. Various standardized quality of life tests are now routinely used in clinical trials involving HD patients. Besides dialysis adequacy, quality of life may also be significantly affected by factors related to organizational issues, for example, travel delays,

waiting time at the dialysis facility for treatment to start, time of dialysis in relationship to work or educational needs, and lack of exercise.

Depression is one of the major mental aspects affecting quality of life and may be assessed separately by validated standardized questionnaires, such as the Beck Depression Index.²⁰ Depression is frequently associated with biochemical evidence of inflammation or infection and may improve with appropriate treatment. One potential way to make some impact on some of these issues is to modify the “assembly line” character of many dialysis centers with variations including physical exercise and occupational therapy programs and opportunities for the patients to have regular meetings with staff to discuss their questions.

Acute Complications During Hemodialysis

Victor F. Seabra, Bertrand L. Jaber

CARDIOVASCULAR COMPLICATIONS

Intradialytic Hypotension

Intradialytic hypotension, which occurs in 10% to 30% of treatments, ranges from asymptomatic episodes to marked compromise of organ perfusion resulting in myocardial ischemia, cardiac arrhythmias, vascular thrombosis, loss of consciousness, seizures, or death. Further, in patients with acute kidney injury, intradialytic hypotension may induce more renal ischemia and retard recovery of renal function. Intradialytic hypotension and postdialysis orthostatic hypotension have been shown to be independent risk factors for mortality.¹ The pathogenesis of intradialytic hypotension is complex² and is summarized in [Figure 91.1](#).

The immediate treatment is to restore the circulating blood volume by placing the patient in the Trendelenburg position, reducing or stopping ultrafiltration, and infusing boluses of 0.9% isotonic saline (100 ml or more, as necessary). Salt-poor albumin offers no advantage over isotonic saline and costs more. Blood flow rate should not be routinely reduced to manage hypotension as it has not been shown to be beneficial. If the blood pump rate is reduced transiently, particular attention should be paid to minimizing underdialysis from such a practice. Because cardiac factors can precipitate intradialytic hypotension, if hypotension is accompanied by chest pain or dyspnea, an electrocardiogram should be obtained to rule out ischemia. Similarly, recurrent and unexplained episodes of hypotension might warrant echocardiography to rule out pericarditis.

Preventive strategies include correction of anemia and hypoalbuminemia and treatment of congestive heart failure or arrhythmias, avoidance of antihypertensive drugs before dialysis, and avoidance of food before and during dialysis. Patients should be counseled to avoid excessive interdialytic weight gain, and accurate assessment of the patient's dry weight is required. Midodrine, an oral selective α_1 -agonist, is a useful preventive therapy.³

Preventive strategies through modification of the dialysis procedure include the use of bicarbonate dialysate, volumetric control of ultrafiltration, sodium modeling, and short daily dialysis.⁴ Online blood volume monitoring and biofeedback techniques have also been used to improve intradialytic cardiovascular stability.⁵ Dialysate cooling to 35.5°C to 36°C, a measure that induces release of catecholamines, resulting in vasoconstriction, may lessen hypotension. This can be achieved through a new device with thermal sensors able to measure blood temperature at the arterial and venous sides of the extracorporeal circuit and

accordingly modify the dialysate temperature. This technique allows isothermic dialysis and has been shown to reduce symptomatic intradialytic hypotension.⁶

Intradialytic Hypertension

Intradialytic hypertension occurs in 8% to 30% of treatments.⁷ Hypertension during or immediately after dialysis constitutes an important risk factor for cardiovascular mortality. Moreover, intradialytic increase in systolic blood pressure is associated with an increased risk of hospitalization or death.⁸

Its mechanism is primarily volume dependent. However, in a number of patients, blood pressure remains elevated despite fluid removal, a syndrome called dialysis-refractory hypertension. These patients are usually young with preexisting hypertension and have excessive interdialytic weight gain and a hyperactive renin-angiotensin system in response to fluid removal.⁹ There may be a lag time of several weeks between achieving dry weight and becoming normotensive.

Erythropoietin and other erythropoiesis-stimulating agents have been associated with a 20% to 30% incidence of new onset or exacerbation of hypertension. Further, among patients receiving intravenous (not subcutaneous) erythropoietin, elevated levels of endothelin-1 (a potent vasoconstrictor) have been shown to correlate with increased blood pressure. Intradialytic hypertension can be precipitated by the use of hypernatric dialysate, which is intended to mitigate the intradialytic decrease in serum osmolality that occurs with the diffusive removal of urea and sodium.¹⁰ Although this approach stabilizes blood pressure during dialysis, hypernatric dialysate results in a positive intradialytic sodium balance and is associated with increased postdialysis thirst, resulting in significant weight gain in the interdialytic period. To circumvent these problems, sodium modeling has been adopted as an approach that uses variable sodium concentrations in the dialysate, generally with sodium reduced in a continuous or stepwise manner from an initial level of 150 to 154 mmol/l to 138 to 142 mmol/l. Other hypothesized mechanisms of intradialytic hypertension include hyperactivity of the sympathetic nervous system¹¹ and increased cardiac output due to fluid removal, particularly among patients with cardiomyopathy.¹² Clinicians should also be aware of possible dialytic removal of certain antihypertensive drugs, such as angiotensin-converting enzyme (ACE) inhibitors and β -blockers.

Increasing hypertension during a dialysis session requires intervention if systolic blood pressure is greater than 180 mm Hg. This is best treated with a centrally acting agent such as clonidine

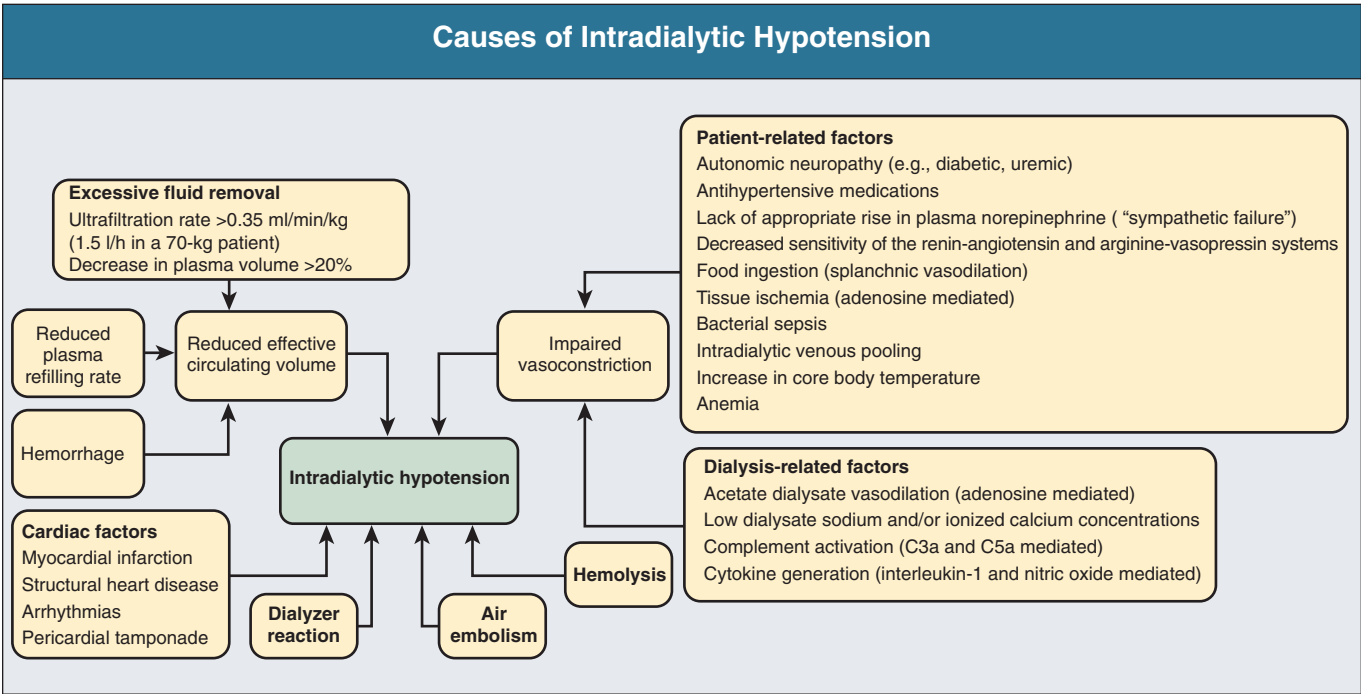

Figure 91.1 Pathogenesis and causes of intradialytic hypotension.

or a short-acting ACE inhibitor such as captopril. Successful treatment of hypertension for a longer period requires an accurate determination of the patient's dry weight and its achievement by gradual ultrafiltration during several weeks of dialysis. Sodium modeling can be instituted, targeting serum sodium concentrations of 135 mmol/l at the end of dialysis; reduce the dry weight in 0.5-kg increments, observe the clinical response, and reevaluate periodically. Once dry weight is achieved, optimization of antihypertensive drug therapy is warranted, including the use of minimally dialyzable or nondialyzable medications such as angiotensin receptor blockers, calcium channel blockers, clonidine, and carvedilol.

Cardiac Arrhythmias

Intradialytic arrhythmias are common and are often multifactorial in origin.^{13,14} Left ventricular hypertrophy, congestive cardiomyopathy, uremic pericarditis, silent myocardial ischemia, and conduction system calcification are frequently encountered in adult dialysis patients. In addition, polypharmacy coupled with the constant alterations in fluid, electrolyte, and acid-base homeostasis may precipitate intradialytic arrhythmias. The range of electrocardiographic abnormalities that may be encountered in renal failure is shown in Figure 91.2. QTc dispersion, the difference between maximum and minimum QTc interval on a standard 12-lead electrocardiogram, is prolonged after hemodialysis (HD) and has been proposed as a prognostic indicator of cardiac complications in dialysis patients.¹⁵

Preventive measures include the use of bicarbonate dialysate and careful attention to dialysate potassium and calcium levels. Use of zero potassium dialysate should be discouraged because of its arrhythmogenic potential, particularly in patients receiving digoxin, should serum potassium concentration decrease to less than 3.5 mmol/l. Serum digoxin levels should be regularly monitored and the need for the drug regularly reassessed.

Electrocardiographic Abnormalities in Renal Failure	
Function	Abnormality Seen in Renal Failure
PR interval	Usually normal; prolongation in long-term hemodialysis Calcification of mitral valve annulus may involve His-bundle giving complete heart block
QRS interval	
Amplitude	Increases during ultrafiltration (correlates with reduction in left ventricular [LV] dimensions) LV hypertrophy (LVH) on voltage criteria found in up to 50%
Duration	Prolonged (within normal range) by hemodialysis Late potentials increased only in patients with preexisting ischemic heart disease Prolonged in hyperkalemia
ST segment	Depression during hemodialysis does not predict coronary artery disease Depression or elevation may occur in hyperkalemia Depression during ambulatory monitoring poorly predictive of coronary artery disease
QTc interval	Increases during hemodialysis (correlates with reduction in [K ⁺] and [Mg ²⁺]) Increased QT dispersion reported in patients on dialysis
T wave	Peaking or inversion may occur in hyperkalemia Inversion in anterolateral leads in LVH with strain pattern
Rhythm	High incidence of atrial and ventricular arrhythmias during hemodialysis

Figure 91.2 Electrocardiographic abnormalities in renal failure. Risk factors include left ventricular dysfunction, wall motion abnormalities, known coronary artery disease, abnormal thallium redistribution tests (even without coronary artery disease), use of cardiac glycosides, and low dialysate potassium concentration.

Sudden Death

Cardiac arrest occurs at a rate of 7 per 100,000 HD sessions and is more common in the elderly, patients with diabetes, and patients using central venous catheters.¹⁶ Some 80% of sudden deaths during dialysis are due to ventricular fibrillation and are more frequently observed after the long interdialytic interval on thrice-weekly dialysis.^{17,18} Although ischemic heart disease increases the risk of sudden death, other catastrophic intradialytic events need to be ruled out. The prompt recognition and treatment of life-threatening hyperkalemia, often encountered in young, noncompliant patients, is imperative. Profound generalized muscle weakness may be a warning sign of imminent life-threatening hyperkalemia.

When cardiopulmonary arrest occurs during dialysis, an immediate decision must be made as to whether the collapse is due to an intrinsic disease or technical errors, such as air embolism, unsafe dialysate composition, overheated dialysate, line disconnection, or sterilant in the dialyzer. Air in the dialysate, grossly hemolyzed blood, and hemorrhage due to line disconnection can be easily detected. However, if no obvious cause is identifiable, blood should not be returned to the patient, particularly if the arrest occurred immediately on initiation of dialysis. A patient exposed to formaldehyde may have complained earlier of burning at the access site. If the possibility of a problem with dialysate composition is remote, blood may be returned to the patient. However, blood and dialysate samples should be immediately sent for electrolyte analysis, the dialyzer and blood lines saved for later analysis, and the dialysis machine replaced until all its safety features have been thoroughly evaluated for possible malfunction. It should be a standard practice to have defibrillators in dialysis units. The management of cardiopulmonary arrest during dialysis should follow the standard principles of cardiopulmonary resuscitation; the diagnosis and management of technical errors are discussed later.

Prevention of sudden cardiac death in HD patients, including the role of implantable defibrillators, is further discussed in Chapter 78.

Pericarditis

The management of pericarditis in dialysis patients is discussed in Chapter 78.

Dialysis-Associated Steal Syndrome

The construction of an arteriovenous fistula or graft frequently results in reduction of blood flow to the hand. Although clinically significant ischemia does not usually result, symptoms are by no means rare, particularly in diabetics or elderly patients with peripheral vascular disease. Dialysis-associated steal syndrome has been reported in 6.4% and 1% of patients with radiocephalic fistulas and grafts, respectively. The clinical presentation, differential diagnosis, and evaluation of dialysis-associated steal syndrome are summarized in Figure 91.3 and are discussed further in Chapter 87.^{19,20}

Treatment depends on the clinical severity of ischemia and vascular access anatomy.²⁰ Severe ischemia can cause irreparable injury to nerves within hours and must be considered a surgical emergency. Mild ischemia, manifested by mild pain during HD, subjective coldness and paresthesias, and objective reduction in skin temperature but with no loss of sensation or motion, is common and generally improves with time.²¹ Patients with mild

Dialysis-Associated Vascular Steal Syndrome
Clinical presentations (symptoms often aggravated on dialysis) Hand numbness, pain, or weakness Coolness of distal arm Diminished pulses Acrocyanosis, gangrene
Differential diagnosis Dialysis-associated cramp Polyneuropathy—diabetes, uremia Entrapment neuropathy— $\text{A}\beta_2\text{M}$ amyloid Reflex sympathetic dystrophy Calciphylaxis
Evaluation of steal severity Pulse oximetry Plethysmography Doppler flow Angiography
Treatment options (depending on severity) Symptomatic (e.g., gloves) Surgical, with preservation of vascular access: banding to reduce flow, DRIL procedure (see Figure 87-9) With loss of vascular access; ligation

Figure 91.3 Dialysis-associated vascular steal syndrome. DRIL, distal revascularization and interval ligation.

ischemia should undergo symptom-specific therapy (e.g., wearing a glove) and frequent physical examination, with special attention to subtle neurologic changes and muscle wasting.²² Failure to improve may require surgical intervention with banding or access correction or ligation. More serious manifestations, such as fingertip necrosis, require ligation of the fistula,²¹ which provides immediate improvement in perfusion but results in the elimination of a site for vascular access and the immediate need to construct another one. Other techniques that do not sacrifice the access and yet improve distal perfusion include ligation of the artery distal to the origin of the fistula or graft with or without establishment of an arterial bypass (see Chapter 87) and narrowing of the fistula or graft to reduce flow, thereby improving distal perfusion. Percutaneous luminal angioplasty or laser recanalization is reserved for patients with inflow or outflow arterial disease. A modified brachiocephalic fistula extension technique, in which the median vein is anastomosed to the radial or ulnar artery just below the brachial bifurcation, is thought to preserve part of the blood supply to the hand and to prevent the arterial steal syndrome.²³ Persistence of symptoms after an apparently successful correction of the vascular access flow should alert the clinician to other unrelated causes.

NEUROMUSCULAR COMPLICATIONS

Muscle Cramps

Muscle cramps occur in 5% to 20% of patients late during dialysis and frequently involve the legs. They account for 15% of premature discontinuations of dialysis.²⁴ Electromyography shows increased tonic muscle electrical activity throughout dialysis, and serum creatine kinase may be elevated.

Although the pathogenesis is unknown, dialysis-induced volume contraction and hypo-osmolality are common predisposing factors. Indeed, the onset of muscle cramps often gives an indication that the target weight has been reached. However, hypomagnesemia and carnitine deficiency may also play a role.

The acute management is directed at increasing plasma osmolality. Cessation of ultrafiltration is not useful. Parenteral infusion of 23.5% hypertonic saline (15 to 20 ml), 25% mannitol (50 to 100 ml), or 50% dextrose in water (25 to 50 ml) is equally effective. However, hypertonic saline may result in postdialytic thirst, and both hypertonic saline and mannitol cause transient warmth and flushing during the infusion. Furthermore, large and repetitive infusions of mannitol may lead to increased thirst, interdialytic weight gain, and fluid overload. Overall, dextrose in water is preferred, particularly in nondiabetics.

Preventive measures include dietary counseling about excessive interdialytic weight gain. In patients without clinical signs of fluid overload, it is reasonable to increase the dry weight by 0.5 kg and to observe the clinical response. Quinine sulfate (250–300 mg) or oxazepam (5 to 10 mg) given 2 hours before dialysis may also be effective. Although the U.S. Food and Drug Administration regards quinine sulfate as both unsafe and ineffective for the prevention of cramps, this drug works well in some patients, and it is used freely in most parts of the world. The use of sodium gradient during dialysis is effective as well. Proposed strategies include starting with a dialysate sodium concentration of 145 to 155 mmol/l and a linear decrease to 135 to 140 mmol/l by the completion of the treatment. A comparison of sodium modeling with an exponential, linear, or step program has yielded similar results.²⁵ In anecdotal reports, 5 mg of enalapril twice weekly may be effective, presumably by inhibiting angiotensin II–mediated thirst. Stretching exercises, creatine monohydrate (12 mg before dialysis),²⁶ and L-carnitine supplementation (20 mg/kg per dialysis session) may also be beneficial.²⁷ An intradialytic blood volume biofeedback control system has been shown to effectively reduce the incidence of muscle cramps.²⁸

Restless Legs Syndrome

Restless legs syndrome is common in dialysis patients. The typical complaint is of crawling sensations in the legs that occur with inactivity, and symptoms may worsen during dialysis. The etiology, prevention, and management of restless legs syndrome are discussed in Chapter 82.

Dialysis Disequilibrium Syndrome

Despite a decline in its incidence, dialysis disequilibrium syndrome (DDS) is still observed sporadically in patients who are initiated on HD on high-flux dialyzers with large surface areas and short dialysis time. Risk factors include young age, severe azotemia, low dialysate sodium concentration, and preexisting neurologic disorders (see Chapter 82).

DDS commonly presents with restlessness, headache, nausea, vomiting, blurred vision, muscle twitching, disorientation, tremor, and hypertension. More severe manifestations include obtundation, seizures, and coma. DDS usually develops toward the end of dialysis but may be delayed for up to 24 hours. Although cerebral edema is a consistent finding on computed tomographic scanning, DDS remains a clinical diagnosis because laboratory tests, including electroencephalography, are non-specific. It is usually self-limited, but full recovery may take several days.

The pathogenesis of DDS is still a subject of debate. The reverse urea effect theory, which proposes that a transient osmotic disequilibrium occurs during dialysis as a result of a more rapid removal of urea from blood than from cerebrospinal fluid, has been disputed.²⁹ In animals undergoing rapid dialysis,

despite the correction of systemic acidosis, a paradoxical cerebrospinal fluid acidosis develops that is aborted by slower dialysis. An additional mechanism is the intracerebral accumulation of idiogenic osmoles, such as inositol, glutamine, and glutamate.

In high-risk patients, preventive measures include the use of volumetric-controlled machines, bicarbonate dialysate, sodium modeling, earlier recognition of uremic states, and earlier initiation of dialysis. In addition, short and more frequent dialysis treatments are recommended with use of small surface area dialyzers and reduced blood flow rates. The target reduction in blood urea should initially be limited to 30%. The prophylactic use of mannitol or anticonvulsants is not recommended.

Seizures

Intradialytic seizures occur in less than 10% of patients and tend to be generalized but easily controlled. However, focal or refractory seizures warrant evaluation for focal neurologic disease, particularly intracranial hemorrhage. Causes of seizures are summarized in Figure 91.4 and are discussed further in Chapter 82.

Treatment of established seizures requires cessation of dialysis, maintenance of airway patency, and investigation for metabolic abnormalities. Intravenous diazepam, alprazolam or clonazepam, and phenytoin may be required. Intravenous 50% dextrose in water should be administered promptly if hypoglycemia is suspected.

Headache

Dialysis headache is common and consists of a bifrontal discomfort that develops during dialysis and may become intense and throbbing, accompanied by nausea and vomiting. It is usually aggravated by the supine position, but there are no visual disturbances.

Although its etiology has not been elucidated, dialysis headache may be a subtle manifestation of DDS or may be related to the use of acetate dialysate. Furthermore, it may be a manifestation of caffeine withdrawal due to dialytic removal of caffeine.

Management consists of oral analgesics (e.g., acetaminophen [paracetamol]). Preventive measures include slow dialysis with reduced blood flow rates, change to bicarbonate dialysate, sodium and ultrafiltration modeling, coffee ingestion during dialysis, and use of reprocessed dialyzers.

HEMATOLOGIC COMPLICATIONS

Complement Activation and Dialysis-Associated Neutropenia

During dialysis with unsubstituted cellulose dialyzers, which are infrequently used nowadays, the free hydroxyl groups present on the membrane cause activation of the alternative pathway of complement.³⁰ This results in activation and increased adherence of circulating neutrophils to the endothelial capillary pulmonary vasculature, leading to transient neutropenia that reaches a nadir after 15 minutes of dialysis, followed by a rebound leukocytosis 1 hour later. Neutropenia has also been detected with other more widely used dialyzer membranes, including cellulose acetate and polysulfone, but to a lesser degree. Although the long-term clinical relevance of this phenomenon remains speculative, its contribution to acute intradialytic morbidity is discussed later.

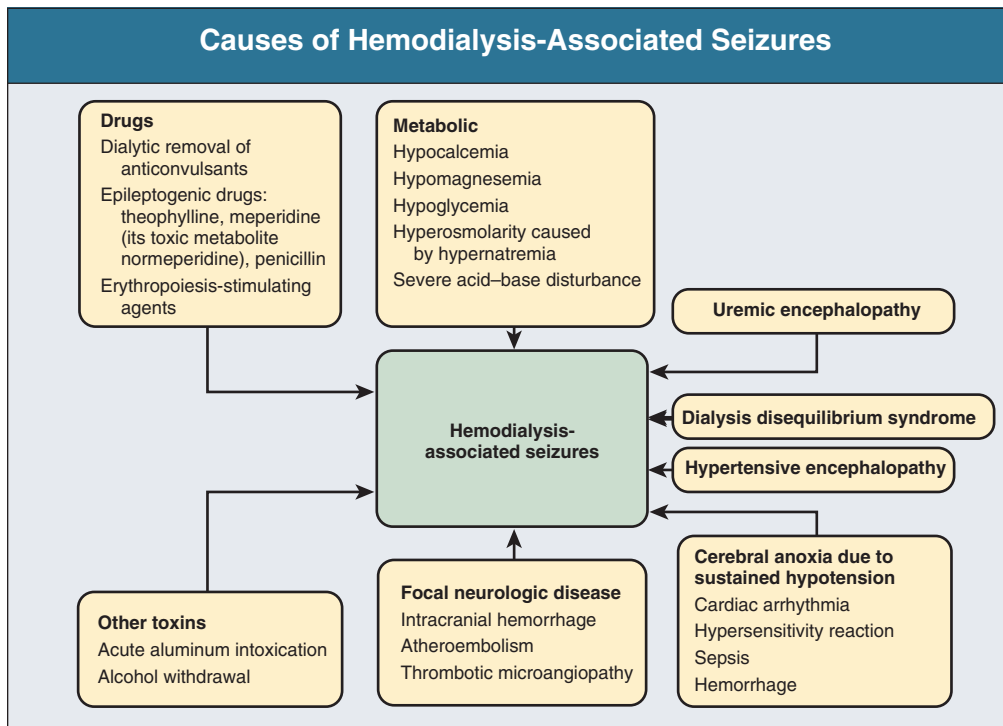

Figure 91.4 Causes of hemodialysis-associated seizures.

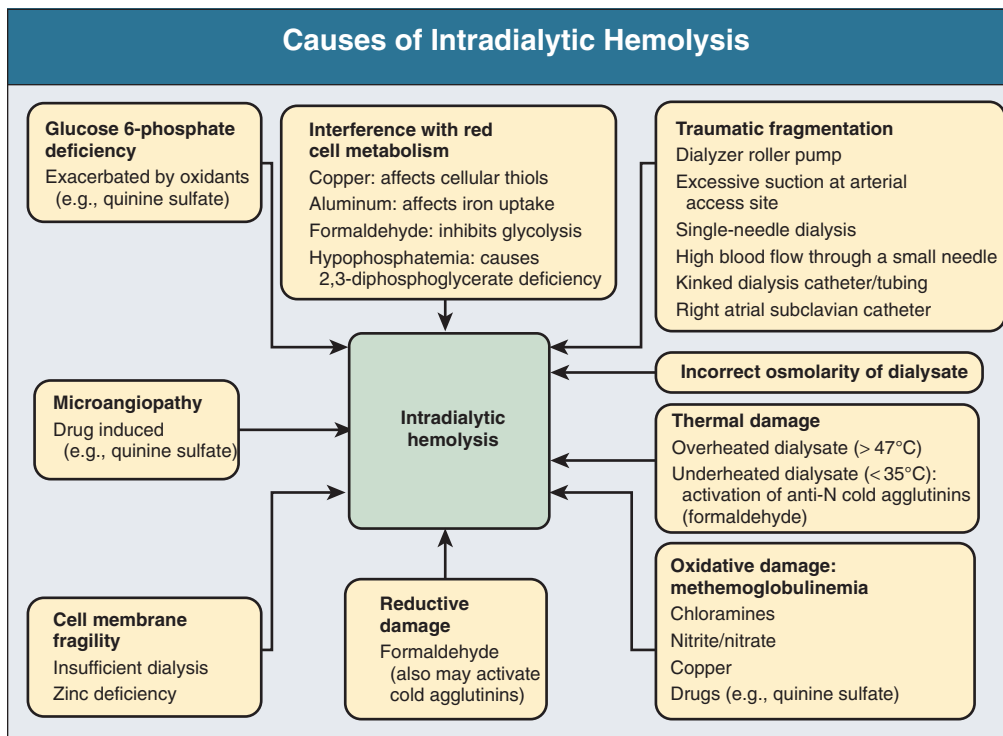

Figure 91.5 Causes of intradialytic hemolysis.

Intradialytic Hemolysis

Acute hemolysis can be due to faulty dialysis equipment, chemicals, drugs, toxins, or patient-related factors (Fig. 91.5).³¹ With the advent of better dialysis equipment and the widespread use of deionization systems, traumatic red blood cell fragmentation caused by poorly designed blood pumps and methemoglobinemia caused by water contamination with chloramine or copper

are never seen today. However, nitrate/nitrite intoxication causing methemoglobinemia still occurs sporadically in patients on home HD who use well water that is contaminated with urine from domesticated animals. Further, during dialyzer reprocessing, formaldehyde retention can result in hemolysis by inducing formation of cold agglutinins or inhibiting red cell metabolism.

The diagnosis of acute hemolysis is evident when grossly translucent hemolyzed blood is observed in the tubing. Patients

with methemoglobinemia have nausea, vomiting, hypotension, and cyanosis, and oxygen therapy does not improve the black blood present in the extracorporeal circuit. Copper contamination should be suspected in the presence of skin flushing and abdominal pain or diarrhea.

Evaluation should include reticulocyte count, haptoglobin, lactate dehydrogenase, blood smear, Coombs test, and measurement of methemoglobin. ^{51}Cr -labeled red blood cell survival and bone marrow examination may occasionally be indicated if there is recurrent hemolysis. More important, analysis of tap water for chloramines and metal contaminants and thorough analysis of the dialysis equipment for clues of increased blood turbulence are recommended.

Hemorrhage

Bleeding complications are commonly related to the use of intradialytic anticoagulation, which further confounds the uremic bleeding diathesis (see Chapter 80).³² In addition, dialysis patients are prone to spontaneous bleeding at specific sites, such as gastrointestinal arteriovenous malformations; subdural, pericardial, pleural, retroperitoneal, and hepatic subcapsular spaces; and the ocular anterior chamber. Despite its limitations, the bleeding time remains the best indicator of hemorrhagic tendency.

In addition to specific measures directed to the site of hemorrhage, reversal of uremic platelet dysfunction is imperative. Strategies include the use of erythropoiesis-stimulating agents or red blood cell transfusions to achieve a hematocrit above 30% to improve rheologic platelet-vessel wall interactions, intravenous conjugated estrogens at 0.6 mg/kg per day for 5 consecutive days, intravenous or subcutaneous 1-deamino-8-D-arginine vasopressin (DDAVP) at 0.3 $\mu\text{g/kg}$ during 15 to 30 minutes, and intravenous infusion of cryoprecipitate (see Fig. 80.4). For patients experiencing severe bleeding, it is advisable to consider heparin-free dialysis, using normal saline flushes every 15 to 30 minutes with ultrafiltration adjustments, regional heparin or citrate anticoagulation, low-molecular-weight heparin, heparin modeling, or prostacyclin. More recently, the use of heparin-bound Hemophan dialyzers has been advocated in patients at risk of bleeding.³³ In patients scheduled for elective surgery or invasive procedures, aspirin should be stopped a week earlier, the dose of anticoagulant reduced to a minimum, and the hematocrit maintained above 30%. In some cases, DDAVP or estrogens may also be required. Tranexamic acid, a potent fibrinolytic inhibitor, has recently been used as an adjuvant treatment to control hemorrhage in dialysis patients.³⁴

Thrombocytopenia

An increasingly important cause of thrombocytopenia in dialysis patients is heparin-induced thrombocytopenia. The diagnosis and management, including alternative strategies for anticoagulation strategies for HD, are discussed in Chapter 80.

PULMONARY COMPLICATIONS

Dialysis-Associated Hypoxemia

In most patients, the arterial PaO_2 decreases by 5 to 20 mm Hg (0.6 to 4 kPa) during dialysis, reaching a nadir at 30 to 60 minutes, and resolves within 60 to 120 minutes after

discontinuation of dialysis. This decrease is usually of no clinical significance to patients unless there is preexisting chronic cardiopulmonary disease.

Hypoventilation is the main implicated factor and is primarily central in origin due to a decrease in carbon dioxide production after acetate metabolism (specific to acetate dialysate), loss of carbon dioxide in the dialyzer (with both acetate and bicarbonate dialysate), and rapid alkalization of body fluids (specific to bicarbonate dialysate, particularly with large surface area dialyzers).³⁵ In addition, acetate-induced respiratory muscle fatigue can lead to hypoventilation, especially in acutely ill patients. Further, a commonly observed ventilation-perfusion mismatch may be due to pulmonary leukoagglutination (due to complement activation) or impaired cardiac output (due to acetate-induced myocardial depression).

In high-risk patients with fluid overload, preventive measures consist of using intradialytic oxygen supplementation, conventional bicarbonate dialysate, and biocompatible membranes. Optimizing hematocrit values and performing sequential ultrafiltration followed by HD may further reduce the likelihood of hypoxemia.

TECHNICAL MALFUNCTIONS

Air Embolism

The most vulnerable source of air entry into the extracorporeal circuit is the pre-pump tubing segment, where significant subatmospheric pressures prevail. However, other sources need to be considered, including intravenous infusion circuits especially with glass bottles, air bubbles from the dialysate, and dialysis catheters. High blood flow rates may allow rapid entry of large volumes of air despite small leaks.

Clinical manifestations depend on the volume of air introduced, the site of introduction, the patient's position, and the speed at which air is introduced.³⁶ In the sitting position, air entry through a peripheral vein bypasses the heart and causes venous emboli in the cerebral circulation. The acute onset of seizures and coma in the absence of precedent symptoms such as chest pain and dyspnea is highly suggestive of air embolism. In the supine position, air introduced through a central venous line will be trapped in the right ventricle, where it forms foam, interferes with cardiac output, and, if it is large enough, leads to obstructive shock. Dissemination of microemboli to the pulmonary vasculature results in dyspnea, dry cough, chest tightness, or respiratory arrest. Further, passage of air across the pulmonary capillary bed can lead to cerebral or coronary artery embolism. In the left Trendelenburg position, air emboli migrate to the lower extremity venous circulation, resulting in ischemia due to increased outflow resistance. Foam may be visible in the extracorporeal tubing, and cardiac auscultation may reveal a peculiar churning sound.

The immediate management of clinically suspected air embolism is summarized in Figure 91.6. Prevention depends primarily on dialysis machines that are equipped with venous air bubble traps and foam detectors located just distal to the dialyzer and a venous pressure monitor at the venous end. The detector is attached to a relay switch that simultaneously activates an alarm, shuts off the blood pump, and clamps the venous blood line if air is detected. Therefore, dialysis should never be performed in the presence of an inoperative air detection alarm system. Glass bottles should be avoided because they create vacuum effects that

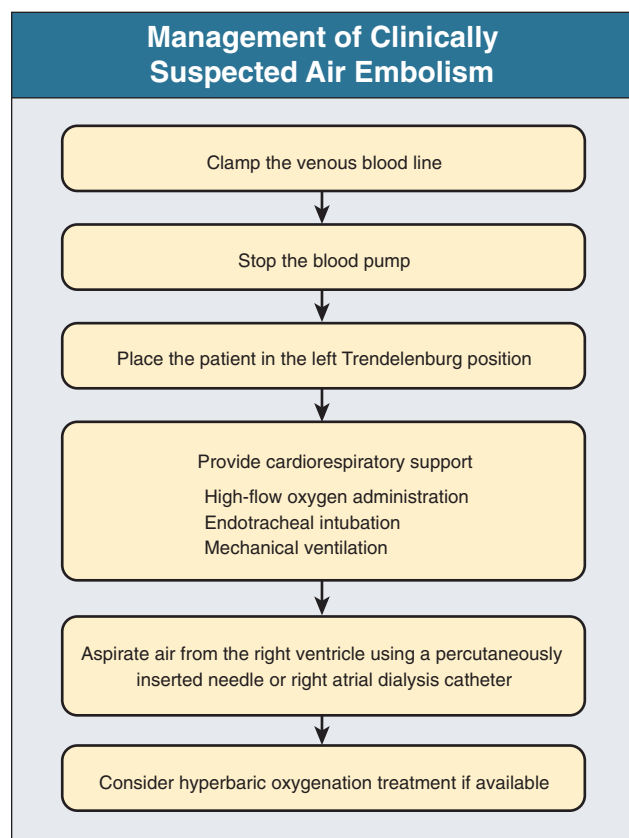

Figure 91.6 Management of clinically suspected air embolism.

can permit air entry into the extracorporeal system. Dialysis catheters should be aspirated and flushed with saline before connection. Dialyzer rinsing, before use, should expand all compartments to remove residual air bubbles.

Incorrect Dialysate Composition

Incorrect dialysate composition results from technical or human errors. Because the primary solutes constituting the dialysate are electrolytes, the dialysate concentration will be reflected by its electrical conductivity. Therefore, proper proportioning of concentrate to water can be achieved by the use of a meter that continuously measures the conductivity of the dialysate solution as it is being fed to the dialyzer. Life-threatening electrolyte and acid-base abnormalities are avoidable if the conductivity alarm is functioning properly and the alarm limits are set correctly. However, in dialysis machines that are equipped with conductivity-controlled mixing systems, the system automatically changes the mixing ratio of the concentrates until the dialysate solution conductivity falls within the set limits. This may inadvertently lead to dialysate without any bicarbonate, with apparently acceptable conductivity. Therefore, if conductivity-controlled systems are used, it is safer to also check the dialysate pH before dialysis. Conductivity monitors can fail or can be improperly adjusted by human error. Therefore, it is important to add human monitoring of dialysate composition before every treatment, whenever a machine has been sterilized or moved about, or whenever a new concentrate is used. Furthermore, many nonstandardized solutions are available, some of which may be used with an inappropriate proportioning

system. Therefore, it is also essential that the supplies match the machine-proportioning ratio for which they were prepared for the appropriate final dialysate composition to be obtained.

Hypernatremia

Hypernatremia occurs when concentrate or the ratio of concentrate to water is incorrect and the conductivity monitors or the alarms are not functioning properly. Hyperosmolality results in intracellular water depletion. Clinical manifestations include thirst, headache, nausea, vomiting, seizures, coma, and death. Aggressive treatment is mandatory and includes cessation of dialysis, hospitalization, and infusion of 5% dextrose in water. Dialysis should be resumed with a different machine; the dialysate sodium level should be 2 mmol/l lower than the plasma level, and isotonic saline should be concurrently infused. Dialysis against a sodium level 3 to 5 mmol/l lower than the serum level may increase the risk of disequilibrium. Ultrafiltration with equal volume replacement with normal saline is another option.

Hyponatremia

Failure to add concentrate, inadequate concentrate to water ratio, or conductivity monitor or alarm malfunction can cause hyponatremia. Hyponatremia can also occur during the course of dialysis with a proportioning system if the concentrate container runs dry and the conductivity set limits are inappropriate. Acute hypo-osmolality causes hemolysis with hyperkalemia and hemodilution of all plasma constituents. Symptoms include restlessness, anxiety, pain in the vein injected with the hypotonic hemolyzed blood, chest pain, headache, nausea, and occasional severe abdominal or lumbar cramps. Pallor, vomiting, and seizures may be observed. Treatment consists of clamping the blood lines and discarding the hemolyzed blood in the extracorporeal circuit. High-flow oxygen and cardiac monitoring are imperative because of hyperkalemia and potential myocardial injury. Dialysis should be restarted with a new dialysate batch containing low potassium, and high transmembrane pressure should be applied to remove excess water. Correction of serum sodium concentration should be achieved by no more than 1 to 2 mmol/l per hour. Anticonvulsants are indicated for seizures and blood transfusions for severe anemia. Successful correction of severe hyponatremia has been reported in a single 3-hour HD session with a dialysate sodium concentration of 135 mmol/l without any adverse neurologic consequences despite a serum sodium correction rate of 3 mmol/l per hour.³⁷ This suggests that elevated blood urea levels might protect uremic patients from the development of demyelinating syndromes when hyponatremia is rapidly corrected.

Metabolic Acidosis

Although acute intradialytic metabolic acidosis can be a manifestation of improper mixing of concentrates or failure of pH monitors, other causes need to be ruled out, including diabetic or alcoholic ketoacidosis, lactic acidosis, toxic ingestions, and dilutional acidosis.³⁸ The diagnosis is usually suggested by the acute onset of hyperventilation during HD and confirmed by laboratory evaluation. In most circumstances, correction of the underlying cause and use of bicarbonate dialysate at the appropriate concentration (35 mmol/l) are adequate measures.

Metabolic Alkalosis

Severe intradialytic metabolic alkalosis is rare and may be due to error in dialysate concentrates, reversed connection of bicarbonate and acid concentrate containers to the entry ports of the dialysis machine, pH monitor malfunction, or use of regional citrate anticoagulation. The most common cause, however, is hydrochloric acid loss as a result of vomiting or nasogastric suction. Attention should also be directed to identification of sources of added alkali.³⁹ Furthermore, the combination of sodium polystyrene sulfonate and aluminum hydroxide can lead to absorption of alkali that is normally neutralized in the small intestine.

Acute treatment is rarely necessary unless a technical error has occurred. Removal of the alkali source is usually sufficient, and H₂ antagonists or proton pump inhibitors may be successful if there is gastric acid loss. The administration of sodium chloride to anephric patients with chloride-sensitive alkalosis will not repair the alkalosis. If a more rapid reduction in serum bicarbonate is desired, modification of the dialysate bath by replacement of alkali with chloride, substitution of bicarbonate with acetate dialysate, use of acid dialysate, and infusion of hydrochloric acid are effective but cumbersome measures. The use of conventional or low-bicarbonate (25 to 30 mmol/l) dialysate is probably as effective.

Temperature Monitor Malfunction

Malfunction of the thermostat in the dialysis machine can result in the production of excessively cool or hot dialysate. Whereas cool dialysate is not dangerous and may have beneficial hemodynamic effects, overheated dialysate can cause immediate hemolysis and life-threatening hyperkalemia, particularly if the dialysate temperature increases to more than 51°C. In such an event, dialysis must be stopped immediately and blood in the system discarded. The patient should be monitored for hemolysis and hyperkalemia. Dialysis should be resumed to cool the patient by use of a dialysate temperature of 34°C to treat hyperkalemia and to allow blood transfusions if necessary. Visual and audible alarms are mandatory to prevent this complication.

Blood Loss

Intradialytic blood loss can result from arterial or venous needle disengagement from the access, separation of the venous or arterial line connections, femoral or central line dialysis catheter perforation or dislodgment, or rupture of a dialysis membrane with or without malfunction of the blood leak detector. Clinical findings include hypotension, loss of consciousness, and cardiac arrest. In addition, after traumatic insertion of a dialysis catheter, blood loss can result in pain or mass from a rapidly expanding hematoma; chest, shoulder, or neck pain from intrapericardial blood loss; back, flank, groin, or lower abdominal pain or distention from retroperitoneal bleeding; or hemoptysis from pulmonary bleeding. Acute management includes the discontinuation of HD, pressure application for local hemostasis, hemodynamic support, oxygen administration, and surgical intervention if needed.

Clotting of Dialysis Circuit

Clotting of the extracorporeal circuit during dialysis is a common practical problem, has many underlying causes, and warrants a

thorough investigation. Technical factors include an inadequate or poor priming technique, resulting in retention of air in the dialyzer, and lack of or inadequate priming of the heparin infusion line. Such operator-induced errors are corrected through ongoing staff education and competency assessment. Incorrect heparin loading dose, insufficient time lapse after loading dose of heparin for systemic anticoagulation to occur, incorrect pump setting for constant heparin infusion, delayed start of the heparin pump, and failure to release the heparin line clamp are important correctable causes of clotting that should also be considered. Vascular access-related problems from inadequate blood flow due to needle or catheter positioning or clotting, excessive access recirculation, and frequent interruption of blood flow due to inadequate delivery or machine alarm situations are additional causes that can result in clotting. Immediate management requires prompt recognition of the underlying cause and implementation of corrective actions, including ongoing heparin dose adjustment and, if indicated, vascular access revision.

DIALYSIS REACTIONS

During HD, blood is exposed to surface components of the extracorporeal circuit, including the dialyzer, tubing, sterilization processes, and other foreign substances related to the manufacturing and reprocessing procedures. This interaction between the patient's blood and the extracorporeal system can lead to various adverse reactions (Fig. 91.7).⁴⁰

Anaphylactic and Anaphylactoid Reactions

Clinical Presentation

Anaphylaxis is the result of an IgE-mediated acute allergic reaction in a sensitized patient, whereas anaphylactoid reactions result from the direct release of mediators by host cells. The onset of symptoms usually occurs within the first 5 minutes of initiation of dialysis, although a delay of up to 20 minutes is possible. Symptoms vary from subtle to severe and include burning or heat throughout the body or at the access site; dyspnea, chest tightness, and angioedema or laryngeal edema; paresthesias involving the fingers, toes, lips, or tongue; rhinorrhea, lacrimation, sneezing, or coughing; skin flushing; pruritus; nausea or vomiting; abdominal cramps; and diarrhea. Predisposing factors include a history of atopy, elevated total serum IgE, eosinophilia, and the use of ACE inhibitors. The etiology of dialysis reactions is diverse and requires a thorough investigation.

First-Use Reactions

The majority of these reactions are ascribed to the manufacturer's dialyzer sterilant ethylene oxide (ETO), which is now rarely used. The potting compound that anchors the hollow fibers in the dialyzer housing acts as a reservoir for ETO and may impede its washout from the dialyzer, leading to sensitization. When it is conjugated to human serum albumin (HSA), ETO acts as an allergen. By use of a radioallergosorbent test (RAST), specific IgE antibodies against ETO-HSA are detected in two thirds of patients with such reactions. However, 10% of patients with no history of dialysis reactions have a positive RAST result.

Reuse Reactions

As most residual ETO is washed out of the dialyzer during first use, reuse reactions are likely to be due to the disinfectants used for dialyzer reprocessing. These agents include formaldehyde,

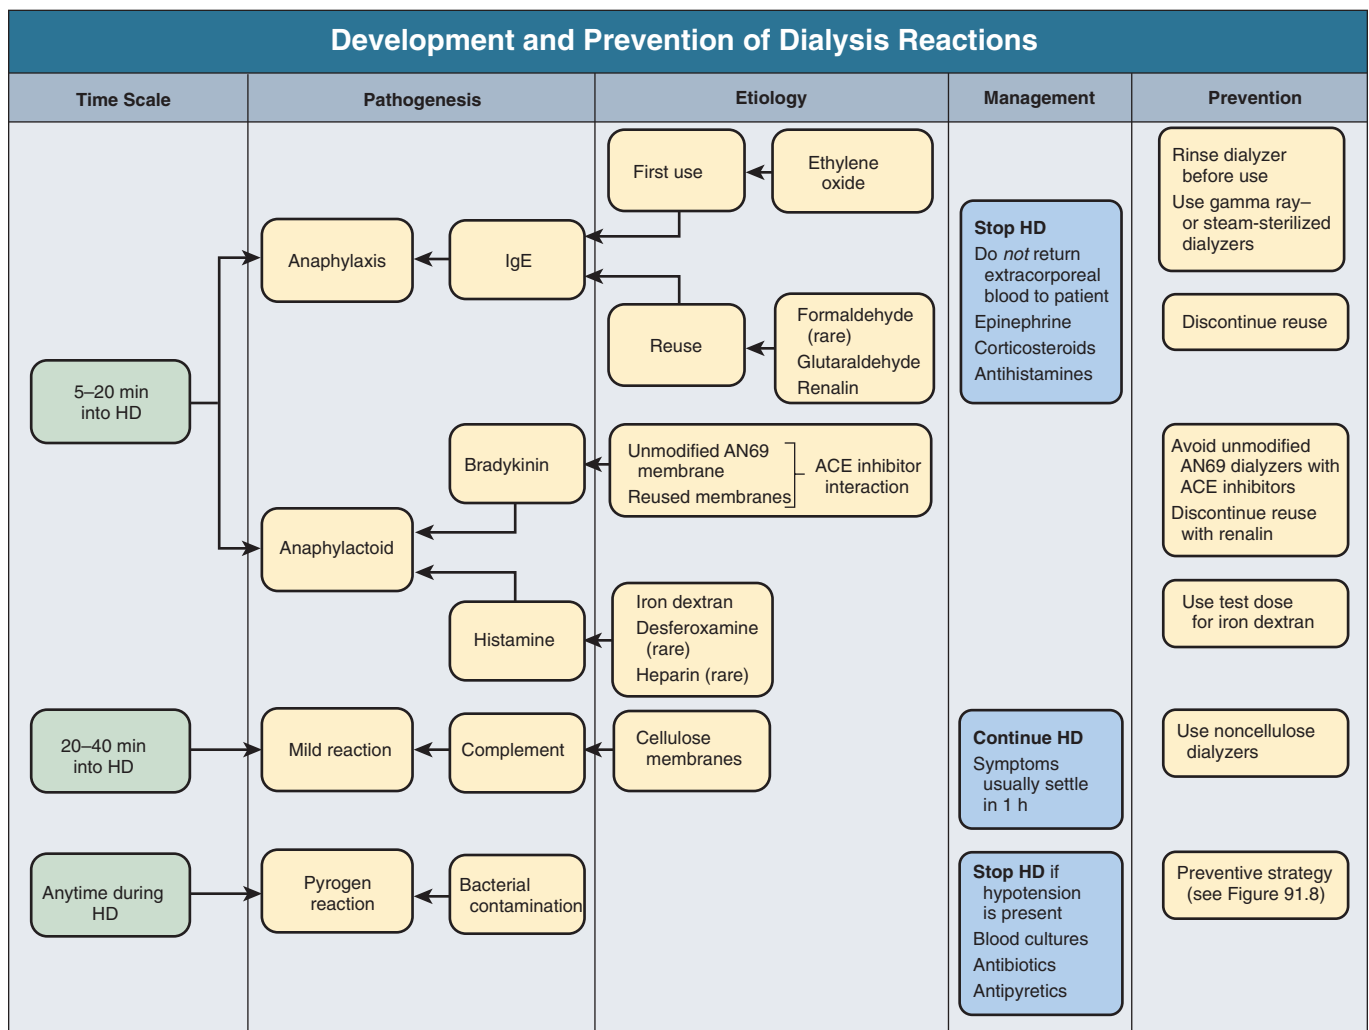

Figure 91.7 Development and prevention of dialysis reactions. ACE, angiotensin-converting enzyme; HD, hemodialysis.

glutaraldehyde, and peracetic acid–hydrogen peroxide (renalin); in allergic patients, specific IgE antibodies against formaldehyde are occasionally detectable.

Bradykinin-Mediated Reactions

In the early 1990s, anaphylactoid reactions appeared in Europe among patients dialyzed with AN69 dialyzers who were also taking ACE inhibitors. Investigation of these incidents revealed that binding of factor XII to this sulfonate-containing, negatively charged membrane resulted in the formation of kallikrein and release of bradykinin, which in turn led to the production of prostaglandin and histamine, with subsequent vasodilation and increased vascular permeability. ACE inactivates bradykinin, and therefore ACE inhibitors can prolong the biologic activities of bradykinin.⁴¹ These membranes have since been chemically modified, thereby reducing this risk.

Anaphylactoid reactions have also been observed in patients taking ACE inhibitors who were dialyzed with membranes that had been reprocessed. Renalin was the sterilant used, and the reactions abated once reprocessing was discontinued, despite continued use of ACE inhibitors. It has been speculated that renalin may oxidize cysteine-containing proteins that are adsorbed on the dialyzer membrane, leading to the formation of cysteine sulfonate and contact activation of factor XII.

Drug-Induced Reactions

Anaphylactoid reactions to parenteral iron dextran occur in 0.6% to 1% of HD patients. Significantly higher rates of anaphylactoid reactions have been observed among users of higher molecular weight compared with lower molecular weight iron dextran.⁴² *In vitro*, dextran produces a dose-dependent basophil histamine release. In light of hypersensitivity reactions, the National Kidney Foundation's Clinical Practice Guidelines recommend that resuscitative medication and personnel trained to evaluate and to resuscitate anaphylaxis should be available whenever a dose of iron dextran is administered.⁴³ Intravenous iron gluconate and sucrose are alternative preparations that have rapidly replaced iron dextran for patients requiring intravenous iron supplementation because of fewer anaphylactoid reactions than with high-molecular-weight dextran. Life-threatening adverse drug events, defined as reactions requiring resuscitative measures, appear to be more frequent among recipients of iron dextran than among recipients of sodium ferric gluconate complex and iron sucrose.^{43–45} Ferumoxytol, a new iron formulation that might be as safe as iron gluconate and sucrose with a better dosing regimen, was recently approved for use in patients with chronic kidney disease.⁴⁶

Hypersensitivity to heparin formulations is rare and usually responds by substitution of beef with pork heparin, or vice versa.

A recent nationwide outbreak in the United States of severe adverse reactions in HD patients was attributed to vials of heparin contaminated with oversulfated chondroitin sulfate.⁴⁷

Treatment and Prevention

Treatment of anaphylactic and anaphylactoid reaction requires the immediate cessation of HD without returning the extracorporeal blood to the patient. Epinephrine, antihistamines, corticosteroids, and respiratory support should be provided, if needed. Specific preventive measures include rinsing the dialyzer immediately before first use, substituting ETO- with gamma ray- or steam-sterilized dialyzers, avoiding unmodified AN69 membranes in patients taking ACE inhibitors, and discontinuing reprocessing procedures in selected cases.

Mild Reactions

Mild reactions occur 20 to 40 minutes after initiation of dialysis with unsubstituted cellulose dialyzers and consist of chest or back pain. Dialysis can be continued as symptoms usually abate after the first hour, suggesting a relation to the degree of complement activation. Indeed, these reactions decrease with the use of substituted and reprocessed unsubstituted cellulose membranes. Oxygen therapy and analgesics are usually sufficient. Preventive measures include automated cleansing of new dialyzers and use of noncellulose dialyzers.

Fever and Pyrogenic Reactions

Fever during dialysis can be the result of either a localized or a systemic infection or excessive microbial contamination of the dialysis apparatus. The latter, known as pyrogenic reaction, is usually a diagnosis of exclusion. Several factors during dialysis place patients at risk of exposure to bacterial products, including contaminated water or bicarbonate dialysate, improperly sterilized dialyzers, use of central venous dialysis catheters, and cannulation of infected arteriovenous grafts or fistulas.⁴⁰ Soluble bacterial products can diffuse across the dialyzer into the blood, resulting in cytokine production and, consequently, pyrogenic reactions. Strategies for the prevention of pyrogenic reactions are summarized in Figure 91.8.⁴⁸

When fever develops during HD, the first step is to address hemodynamic stability. If the patient is hypotensive, administration of fluids, cessation of ultrafiltration, and discontinuation of dialysis are often required, and refractory hypotension suggesting severe sepsis should trigger hospitalization.

The next step is to identify a potential source of infection. Careful examination of the dialysis vascular access is warranted. If a non-vascular access-related infectious source is identified, specific therapy should be instituted on the basis of the working diagnosis. Nontunneled and tunneled central venous dialysis catheters should always be suspected as a likely cause of infection, even in the absence of local signs of infection such as erythema and exit site drainage. Nontunneled catheters with evident signs of infection at the insertion site should be removed and the tip cultured.

Antipyretics should be administered and blood culture specimens should be obtained before initiation of antibiotic therapy. The initial choice of antibiotics should include vancomycin plus empiric gram-negative bacterial coverage (e.g., cefepime), and the regimen should be adjusted according to the culture results.⁴⁹

In the presence of a dialysis catheter, paired blood culture specimens should be obtained from both a peripheral vein

Strategies to Prevent Bacterial Contamination		
Strict adherence to the AAMI standards		
Type of Fluid	Microbial Count	Endotoxin
Water products	<200 cfu/ml	<2 EU
Dialysate	<2000 cfu/ml	No standard
Reprocessed dialyzers	No growth	—
Use appropriate germicide 4% formaldehyde* 1% formaldehyde heated to 40°C† Glutaraldehyde† Hydrogen peroxide-peracetic acid mixture (renalin)† Heat sterilization (105°C for 20 hours) for reprocessing of polysulfone membranes†		
Wash and rinse the vascular access arm with soap and water		
Prior to cannulation, inspect vascular access for local signs of inflammation		
Scrub the skin with povidone-iodine or chlorhexidine and allow to dry for 5 minutes prior to cannulation		
Record temperature before and after dialysis		
When central delivery system is used Clean and disinfect connecting pipes regularly Remove residual bacteria or endotoxin by additional filtration		
When single-patient proportioning dialysis machine is used Freshly prepare bicarbonate dialysate on a daily basis Discard unused solutions at the end of each day Rinse and disinfect containers with fluids that meet AAMI standards Air-dry containers prior to dialysate preparation		
Follow manufacturer's guidelines for use of preservative-free medications		

Figure 91.8 Strategies to prevent bacterial contamination. *A minimum of 11- or 24-hour exposure to peracetic acid or formaldehyde is required, respectively. †These germicides are equivalent or superior to 4% formaldehyde. The action level for the total viable microbial count in the product water and conventional dialysate is 50 cfu/ml, and the action level for the endotoxin concentration is 1 EU/ml. and the catheter lumen, and the aforementioned broad-spectrum antibiotic regimen should be initiated. Although the use of antibiotic lock solutions has recently emerged as an adjunct therapy aimed at preservation of the dialysis catheter, this approach warrants further investigation.^{49,50} In the case of a catheter-related *Staphylococcus aureus* infection, the use of an antibiotic lock has been associated with a cure rate of less than 55%,⁵¹ arguing for the removal of the dialysis catheter in this setting, performance of transesophageal echocardiography to rule out endocarditis, and completion of at least 14 days of antibiotic therapy.⁴⁹

An outbreak of bacteremia among several dialysis patients involving a similar organism should prompt a thorough search for bacterial contaminants in the dialysis equipment.⁴⁰ Attention should also be paid to single-use vials that are punctured several times, such as erythropoietin, which has been linked to an outbreak of blood stream infection.⁵²

Investigation of a Dialysis Outbreak

Although causes of dialysis outbreaks are usually easily identifiable, many times the reason for the outbreak is less clear, such as water contamination with bacterial toxins,⁵³ medication chemical impurities,⁴⁷ bacterial contaminants,⁵² systemic embolization of degraded dialyzer membrane polymer due to prolonged or improper storage,⁵⁴ and hemolysis due to faulty blood tube sets.⁵⁵ Investigation of a dialysis outbreak requires a methodical

approach including a critical review of the medical records and the various steps of the dialysis procedure (Fig. 91.9).

MISCELLANEOUS COMPLICATIONS

Postdialysis Fatigue

An ill-defined “washed out” feeling or malaise during or after HD is a common nonspecific symptom that is observed in about one third of patients⁵⁶ and has multifactorial origins. Reduced cardiac output, peripheral vascular disease, depression, poor conditioning, postdialysis hypotension, hypokalemia or hypoglycemia, mild uremic encephalopathy, myopathy due to carnitine deficiency, and membrane bioincompatibility through cytokine production have all been incriminated. The use of glucose or bicarbonate dialysate and L-carnitine supplementation (20 mg/kg per day) has been shown to improve postdialysis well-being. A recent trial of thrice-weekly L-carnitine at 20 mg/kg for 6 months resulted in a marked decrease in C-reactive protein level, which was paralleled by an increase in body mass index.⁵⁷ To date, however, there are insufficient data to support the use of L-carnitine to improve quality of life in unselected dialysis patients.⁴³

Compared with thrice-weekly HD, more frequent dialysis, including short daily and nocturnal HD, has been associated with a marked shortening in the time it takes for patients to recover from a dialysis session and to resume their daily activities, which is a surrogate for postdialysis fatigue.⁵⁸

Pruritus

Pruritus is common. The etiology is often multifactorial, including xerosis, hyperparathyroidism, neuropathy, derangements in the immune system, and inadequate dialysis. In many cases, pruritus is more severe during or after dialysis and may be an allergic manifestation to heparin, ETO, formaldehyde, or acetate. In this

subgroup of patients, use of gamma ray-sterilized dialyzers, discontinuation of formaldehyde use, switching to bicarbonate dialysate, and use of low dialysate calcium and magnesium might result in cessation of itching. Eczematous reactions to antiseptic solutions, rubber glove or puncture needle components, puncture needles, or cellophane used to secure dialysis needles should also be considered.⁵⁹

Therapies include the use of emollients and antihistamines, activated charcoal, ultraviolet therapy, sunbathing, ketotifen (a mast cell stabilizer), erythropoietin therapy, topical capsaicin, and topical tacrolimus ointment. Dialysis adequacy should always be assessed. The management of uremic pruritus is discussed further in Chapter 84 (see Fig. 84.3).

Priapism

Priapism occurs in less than 0.5% of male HD patients. It is not related to sexual activity and occurs while the patient is on dialysis. The patient is usually awakened from sleep by a painful erection. Although the majority of cases are idiopathic, secondary causes include heparin-induced hyperviscosity; high hematocrit due to androgen or epoetin therapy; dialysis-induced hypoxemia and hypovolemia due to excessive ultrafiltration, particularly in African American men with sickle cell disease; and use of α -blockers, such as prazosin, or an antidepressant, such as trazodone.

Urologic referral is mandatory. Acute treatment consists of corporal aspiration and irrigation. Although surgical bypass provides venous egress from the corpora cavernosa, secondary impotence commonly develops but may be effectively treated by a penile prosthesis.

Hearing and Visual Loss

Intradialytic hearing loss may be due to bleeding in the inner ear as a consequence of anticoagulation or cochlear hair cell injury from edema.

Intradialytic visual loss is rare but can be caused by central retinal vein occlusion, precipitation of acute glaucoma, ischemic optic neuropathy secondary to hypotension, or Purtscher-like retinopathy secondary to leukoembolization.

Concomitant ocular and hearing impairment can occur after the use of outdated cellulose acetate dialyzer membranes.⁵⁴

Peritoneal Dialysis: Principles, Techniques, and Adequacy

Bengt Rippe

Peritoneal dialysis (PD) is presently used by ~170,000 end-stage renal disease (ESRD) patients worldwide, representing approximately 8% of the total dialysis population.¹ In PD, the peritoneal cavity, which is the largest serosal space in the body, is used as a container for 2 to 2.5 liters of sterile, usually glucose-containing dialysis fluid, which is exchanged four or five times daily through a permanently indwelling catheter. The dialysis fluid is provided in plastic bags. The peritoneal membrane, by the peritoneal capillaries, acts as an endogenous dialyzing membrane. Across this membrane, waste products diffuse to the dialysate; excess body fluid is removed by osmosis induced by the glucose or another osmotic agent in the dialysis fluid, usually denoted ultrafiltration (UF). PD is usually provided 24 hours a day and 7 days a week in the form of continuous ambulatory peritoneal dialysis (CAPD). Approximately one third of the patients in most centers are on automated peritoneal dialysis (APD, sometimes also referred to as continuous cycler-supported peritoneal dialysis), in which nightly exchanges are delivered through an automatic PD cycler. The use of PD as a modality for ESRD treatment varies widely among countries, mostly because of nonmedical factors, such as the reimbursement policy. In one study, 81% of all dialysis patients in Hong Kong were treated with CAPD or APD in 2006, followed by Mexico (71%) and New Zealand (39%), whereas PD was used by only 7.5% in the United States and by 4.8% in Germany.¹

ADVANTAGES AND LIMITATIONS OF PERITONEAL DIALYSIS

Assuming that the patients or their care givers are competent to undertake PD, the only absolute contraindications are large diaphragmatic defects, excessive peritoneal adhesions, surgically uncorrectable abdominal hernias, and acute ischemic or infectious bowel disease. These and other relative contraindications are discussed further in Chapter 93. PD is best used for patients with some residual renal function, although anuric patients may also do well. Most patients who start PD will eventually, after several years, transfer to other modalities of renal replacement therapy, such as hemodialysis (HD), if adequacy cannot be maintained or because of other complications, such as recurrent peritonitis or exit site or catheter problems. Only rarely do HD patients transfer to PD.

PD offers a number of advantages over HD, at least during the first 2 or 3 years of treatment. First, PD represents a “slow,” continuous, “physiologic” mode of removal of small solutes and excess body water, associated with relatively stable blood

chemistry and body hydration status. Second, there is no need for vascular access. The absence of vascular access and the absence of the blood-membrane contact of HD make catabolic stimuli less prominent in PD than in HD. This, and the continuous nature of PD, may be the major reason that the small solute clearance needed to yield an adequate dialysis is only ~50% of that in HD. Thus, for the same protein intake in PD compared with HD, the need for clearance of uremic waste products is reduced. Furthermore, residual renal function is better preserved in PD patients than in HD patients.

PD is a home-based therapy, and most patients are trained to do the bag exchanges themselves. In general, home dialysis patients have a better quality of life than those on other types of dialysis. The number of hospital visits is reduced and the ability to travel is increased. There is also some evidence that PD patients may be better candidates than HD patients for transplantation; several studies have shown a lower incidence and severity of delayed graft function in PD patients after transplantation.² In children, PD (usually APD) is the preferred dialysis modality because it is noninvasive and socially acceptable, reducing hospital visits and allowing the child to attend school. Advocates of PD often recommend that renal replacement therapy begin with PD according to the patient's choice and then proceed, as required when residual renal function declines, to HD or transplantation. PD should thus be regarded as part of an “integrated” renal replacement therapy together with HD and transplantation.³ Factors influencing the choice of dialysis modality between PD and HD as well as global variations in the use of PD are discussed further in Chapter 86.

PRINCIPLES OF PERITONEAL DIALYSIS

The Three-Pore Model

The major principles governing solute and fluid transport across the peritoneal membrane are *diffusion*, driven by concentration gradients, and *convection* (filtration or UF), driven by osmotic or hydrostatic pressure gradients. The barrier separating the plasma in the peritoneal capillaries from the fluid in the peritoneal cavity is represented by the capillary wall and the interstitium. The interstitium can be regarded as a barrier coupled in series with that of the capillary wall; the mesothelium lining the peritoneal cavity is of much lesser significance as a transport hindrance.

For the transport of fluid (UF) and of large solutes, the capillary wall is by far the dominating transport barrier. However, for small solute diffusion, the interstitium accounts for approximately one third of the transport (diffusion) resistance. The

Figure 92.1 Three-pore model. The small pores in the middle represent the major pathway across the peritoneum through which small solutes move by diffusion and water moves by convection driven by hydrostatic, colloid osmotic, and crystalloid osmotic pressure differences. Across large pores (to the right), macromolecules move out slowly by convection from plasma to the peritoneal cavity. The smallest pores (to the left) are represented by aquaporins permeable to water but impermeable to solutes. Water moves here exclusively by crystalloid osmotic pressure.

Figure 92.2 Light microscopic section of a peritoneal membrane with capillaries and venules (to the right) in an “amorphous” interstitium. The peritoneum is lined by a thin layer of mesothelium (arrows). Capillaries and venules as well as the mesothelium are immunocytochemically stained for aquaporin-1 (brownish). (From reference 45.)

permeability of the capillary wall can be described by a three-pore model of membrane transport (Fig. 92.1).^{4,5} In the capillary wall, the major route for small solute and fluid exchange between the plasma and the peritoneal cavity is the space between individual endothelial cells, the so-called interendothelial clefts. The functional radius of the permeable pathways in these clefts, denoted small pores, is 40 to 50 Å, slightly larger than the radius of albumin (36 Å). The size of these pores markedly impedes the transit of albumin and completely prevents the passage of larger molecules (e.g., immunoglobulins and α_2 -macroglobulin). However, larger proteins can transit through very rare large pores (radius ~250 Å) in capillaries and postcapillary venules. The large pores constitute only 0.01% of the total number of capillary pores, and the transport across them occurs by hydrostatic pressure-driven unidirectional filtration from the plasma to the peritoneal cavity. In addition, the capillary wall has a high permeability to osmotic water transport through “water-only pores” of radius ~2 Å, present in the endothelial cell membranes. These pores have been identified as aquaporin 1 (AQP1) channels (Fig. 92.2).⁶

Fluid Kinetics

Under normal (non-PD) conditions, most transport occurs through the small pores. Only 2% of peritoneal water transport occurs by AQP1. In PD, fluid removal is markedly enhanced by infusion of a hyperosmolar dialysate into the peritoneal cavity. The type of osmotic agent used markedly affects the mechanism of osmosis. Very small osmotic agents (e.g., glycerol) will exert a rather low osmotic effect on the small pores and thereby act primarily on AQP1 channels. In contrast, glucose will induce fluid flow through both AQP1 (~40%) and small pores (~60%), whereas large molecules, such as polyglucose (icodextrin), will remove fluid mainly through small pores (~90%). Thus, glucose osmosis will result in a rapid dilution of the peritoneal dialysate, as reflected by a fall in sodium concentration (sodium sieving) during the first 2 hours of the dialysate dwell, because of relatively large transport through the water-only AQP1 channel; this tends to be corrected later as diffusion across the small pores eventually increases the sodium concentration to that in the plasma.

Glucose, the commonly used osmotic agent, is usually available at three concentrations: 1.36%, 2.27%, and 3.86%. Figure 92.3A demonstrates the intraperitoneal fluid kinetics, computer simulated by use of the three-pore model, during 12 hours of dwell time with these three solutions. Glucose is an intermediate-size osmolyte with a low osmotic efficiency (osmotic reflection coefficient $\sigma = 0.03$) across small pores, whereas glucose is 100% efficient as an osmotic agent across AQP1 ($\sigma = 1$). For that reason, glucose will markedly (30-fold) boost the transport of fluid through aquaporins and thus redistribute fluid transport away from the small pores toward AQP1, resulting in significant sodium sieving. For example, for 3.86% glucose in the PD solution, the dialysate sodium concentration will drop from 132 to 123 mmol/l in 60 to 100 minutes, which later increases toward plasma sodium concentration (Fig. 92.3B). On the other hand, icodextrin, with an average molecular weight of 17 kd, has a high osmotic efficiency ($\sigma \sim 0.5$) across small pores and in relative terms is rather inefficient across aquaporins. Hence, during icodextrin-induced osmosis, only a very minor fraction of the UF will occur through AQP1, producing insignificant sodium sieving (see Fig. 92.7B).

In addition to the size of the osmotic agent, the degree of sodium sieving is dependent on the presence and quantity of AQP1 and also on the total rate of net UF (which is mainly determined by the glucose concentration) and the diffusion capacity of sodium. A high rate of small solute transport, and thereby of sodium diffusion, in so-called fast transporters will show up as rapid equilibration of small solutes (creatinine and glucose) in the peritoneal equilibration test (see later discussion) and will also reduce sodium sieving.

In the absence of an osmotic agent in the PD fluid, the dialysate would be reabsorbed to the plasma within a few hours, mainly driven by the difference in colloid osmotic pressure between plasma and the peritoneum. This absorption will, to a major extent, occur through small pores, whereas ~30% of the peritoneal fluid will be removed by lymphatic absorption. The partial fluid flows in the peritoneal membrane modeled across different fluid conductive pathways in the three-pore model (for 3.86% glucose) are shown in Figure 92.4. It is the presence of relatively high concentrations of glucose in the peritoneal fluid that prevents the reabsorption of fluid to the plasma during the first few hours of the dwell.

Patients who have a high rate of sodium diffusion (fast transporters) will have more difficulty in achieving effective fluid

Figure 92.3 **A, Ultrafiltration as a function of dwell time.** Net ultrafiltration volume (UFV) as a function of dwell time for 3.86% (yellow line), 2.27% (green line), and 1.36% (blue line) glucose, computer simulated by the three-pore model of peritoneal transport. **B, Dialysate sodium concentration as a function of dwell time.** Dialysate sodium concentration as a function of dwell time for 3.86% (yellow line), 2.27% (green line), and 1.36% (blue line) glucose, computer simulated according to the three-pore model of peritoneal transport.

Figure 92.4 **Peritoneal volume flows as a function of dwell time.** Peritoneal volume flows as a function of dwell time for 3.86% glucose partitioned among aquaporins, small pores, large pores, and lymphatic absorption. The small-pore volume flow is initially approximately 60% of total volume flow and becomes negative after peak time (220 minutes). The aquaporin-mediated water flow becomes slightly negative after approximately 250 minutes. The large-pore volume flow is negligible and remains constant throughout the dwell, as does lymphatic absorption (0.3 mL/min).³³

removal compared with slow transporters. In fast transporters, the maximum UF volume is reduced and the peak of the UF versus time curve occurs earlier. There is usually also a more rapid reabsorption of fluid in the late phase of the dwell. The issue of fluid loss from the peritoneum is controversial, however, because some authors claim that the peritoneal fluid loss occurring in the late phase of the PD dwell is dominated by lymphatic absorption.⁷

Effective Peritoneal (Vascular) Surface Area

The functional surface area of the peritoneum reflects the “effective” surface area of the peritoneal capillaries.⁸ The transport of small solutes, such as urea, creatinine, and glucose, is partly limited by the degree of perfusion of these capillaries, the “effective” peritoneal membrane blood flow. Furthermore, as mentioned before, some of the diffusion resistance for the

smallest solutes (urea and creatinine) is located in the interstitium. Vasodilation of arterioles results in an increase in the number of effectively perfused capillaries, whereas vasoconstriction results in a reduction. These alterations often occur without large changes in the fluid “permeability” (hydraulic conductance, L_pS) of the peritoneum. Thus, during vasodilation or vasoconstriction, there is usually a dissociation between changes in the permeability–surface area product (PS or mass transfer area coefficient [MTAC]) for small solutes and changes in L_pS of the membrane. Vasodilation, with recruitment of capillary surface area, occurs early in the dwell when glucose is used as the osmotic agent, causing early, transient increases in PS.⁹

Peritonitis is also associated with marked vasodilation, again leading to increases in small solute PS, in the absence of large changes in L_pS , during the first 60 to 100 minutes of the dwell. However, in some subjects with peritonitis, an increase in L_pS will result in relative increased fluid transport across the small pores. Furthermore, there is usually an opening of large pores in the capillaries (and postcapillary venules), resulting in enhanced leakage of macromolecules (e.g., albumin and immunoglobulins) from plasma to peritoneum. Peritonitis may thus result in a relative difficulty in removal of fluid (due to rapid dissipation of intraperitoneal glucose), a reduced sodium sieving (due to the reduced UF and increased sodium diffusion), and a markedly increased leakage of proteins to the dialysate.

The contact area between the dialysate and the peritoneal tissue varies according to posture and fill volume. Adult subjects usually tolerate 2 to 2.5 liters of instilled volume. An intraperitoneal hydrostatic pressure of less than 18 cm H₂O (supine position) is usually tolerated.¹⁰ At higher pressures (>18 cm H₂O), the patient usually feels some discomfort. At intraperitoneal volumes of less than 2 liters, there is a reduction in small solute PS, whereas PS is only moderately increased at high fill volumes. Overall, an increased fill volume implies a more efficient exchange with regard to both small solute exchange and UF, the latter being much more pronounced for hypertonic solutions.¹¹ For a long time, it was thought that increased fill volumes would directly affect peritoneal fluid reabsorption by the hydrostatic pressure effect (increases in intraperitoneal hydrostatic pressure). However, because 80% of any increase in intraperitoneal hydrostatic pressure is transmitted by vein compression back to the capillaries, the actual changes in the transcapillary hydrostatic pressure gradient, which governs UF, will be rather small.¹² On the other hand, because an elevated intraperitoneal hydrostatic pressure will cause some peritoneal tissue edema and hence a lower tissue oncotic pressure, an elevated intraperitoneal hydrostatic pressure may actually (moderately) increase fluid reabsorption across the peritoneal capillaries.¹³

PERITONEAL ACCESS

The key to successful chronic PD is a safe and permanent access to the peritoneal cavity (Fig. 92.5). Despite improvements in catheter survival during the past few years, catheter-related complications still occur, causing significant morbidity and sometimes forcing the removal of the catheter. Catheter-related problems are a cause of permanent transfer to HD in up to 20% of all patients. Most catheters nowadays are derived from that originally devised by Tenckhoff and Schechter.¹⁴ The Tenckhoff catheter is a Silastic tube with side holes along its intraperitoneal portion. There are usually one or two Dacron cuffs, allowing tissue ingrowth, which secures the catheter in place and prevents pericatheter leakage and infection. The Tenckhoff catheter is

Figure 92.5 A recently implanted peritoneal dialysis catheter *in situ*. Note the subumbilical midline scar where the catheter enters the peritoneal cavity (arrow).

Figure 92.6 Common types of peritoneal dialysis catheter.

straight, having one cuff lying on the peritoneum, with the catheter tip pointing in the caudal direction; the outer cuff is close to the skin exit. Several centimeters of the catheter is thus located transcutaneously. There have been a variety of catheter designs based on the original Tenckhoff catheter. Intraperitoneal and transcutaneous catheter modifications continue to appear, indicating that no single design is perfect (Fig. 92.6). A number of studies report less frequent catheter drainage failures with use of the arcuate “swan neck” catheter (see Fig. 92.6) compared with straight catheters. The swan neck catheter appears superior to a straight catheter when it is not tunneled through an arcuate pathway with a downwardly directed exit site. A cranially directed exit site may result in an increased risk of exit site infection. However, previous catheter studies have not taken into account confounding factors such as nasal carriage of *Staphylococcus aureus* and comorbid conditions such as diabetes mellitus, both known as risk factors for exit site infection, which may put these results into doubt. Thus, there is no hard evidence that any of the

modified catheters on the market is actually superior to the original (one- or two-cuff) Tenckhoff catheter.¹⁵

Ideally, catheter insertion should be undertaken by an experienced operator, under operating room sterile conditions. In various centers, that operator may be a surgeon or a nephrologist trained in interventional nephrology techniques. Presurgical assessment for herniation or any weakness of the abdominal wall is essential; if present, it may be possible to correct this at the time of catheter insertion. Before the operation, eradication of nasal carriage of *S. aureus* with locally applied antibacterials (such as mupirocin) significantly reduces exit site infection rates. A single preoperative intravenous dose of a first- or second-generation cephalosporin is also recommended. To avoid development of vancomycin-resistant enterococcus, vancomycin should not be used as a prophylactic agent. Several placement techniques have been described and practiced: surgical mini-laparotomy and dissection, blind placement using the Tenckhoff trocar, blind placement using a guide wire (Seldinger technique), mini-trocar peritoneoscopy placement, and laparoscopy. These techniques are discussed further in Chapter 88.

TECHNIQUES OF PERITONEAL DIALYSIS

In CAPD, 2 to 2.5 liters of dialysis fluid is exchanged with the peritoneal cavity four or five times daily. In 4 to 5 hours, there is nearly full (95%) equilibration of urea and approximately 65% equilibration of creatinine; the glucose gradient has dissipated to approximately 40% of the initial value. For glucose as an osmotic agent, 4 to 5 hours is a suitable dwell time, although for night dwell exchanges, longer dwell times can be accepted (8 to 10 hours). Furthermore, there is room for individual exchange schedules that can be adjusted to suit the individual patient's convenience. Dwell times shorter than 4 to 5 hours can be performed with a machine (cycler) and can be used when the patient needs to reduce intraperitoneal volume, for example, to minimize leakage. This is often the case in conjunction with catheter insertion, hernia repair, or abdominal operations. Rapid exchanges may also be required during treatment of peritonitis or in patients with fluid overload when the patient's hydration status needs to be corrected rapidly.

Nowadays, double-bag systems (so-called Y systems) are in general use according to the principle "flush before fill." The double-bag system contains the unused dialysis fluid connected to an empty sterile drain bag by a Y-set tubing system. After the patient has connected the system and flushed the connection (for 2 or 3 seconds), a frangible (breakable) pin to the drain bag is opened, and the peritoneal cavity is drained during 10 to 15 minutes to fill the drain bag. This bag is then clamped, and the "fresh" bag is opened to fill the peritoneal cavity during another 10 to 15 minutes. The time for exchange (instillation and drainage), if the catheter is in good order, should not exceed a total of 30 minutes. The first 1.6 to 1.8 liters will usually drain rapidly (at ≥ 200 ml/min), whereas the last 200 to 300 ml will drain much more slowly. The "breakpoint" between the rapid and the slow phases may vary markedly from individual to individual.

APD is usually performed with a cycler overnight (8 to 10 hours), during which large volumes (10 to 20 liters) can be exchanged. During daytime, the APD patient usually has a so-called wet day, that is, a long dwell, usually with icodextrin as the osmotic agent in the dialysis fluid. Some patients with nightly APD perform one daily exchange so that there are two long (6 to 8 hours) daily dwells. Most cyclers can be programmed to vary

inflow volume, inflow time, dwell time, and drain time. Cyclers usually warm the fluid before inflow, and they also monitor outflow volume and the excess drainage (UF volume). Current APD machines have alarms for inflow failure, overheating, and poor drainage. Some cyclers interrupt drainage at the breakpoint between the fast and slow phases to make the exchange more efficient. Another way to accelerate exchanges is to allow a considerable "sump volume" in the peritoneal cavity by not letting all the fluid drain; subsequent inflow volumes are proportionally reduced, and after a number of cycles, complete drainage occurs. This technique is called tidal PD.

The exchange volume should be adjusted according to the patient's size. Adult patients weighing less than 60 kg should start with 1.5-liter bags. The average patient (60 to 80 kg) should receive 2-liter exchanges; and if the patient weighs more than 80 kg, 2.5 liters should be used. If pressure monitoring systems are available, the intraperitoneal hydrostatic pressure may inform the choice of exchange volume. In the supine position, most patients have an intraperitoneal hydrostatic pressure of 12 cm H₂O. If the intraperitoneal hydrostatic pressure is higher than 18 cm H₂O, the patient usually feels some discomfort.

PERITONEAL DIALYSIS FLUIDS

The majority of PD fluids used today have the composition of a lactate-buffered, "balanced" salt solution devoid of potassium, with glucose (1.36%, 2.27%, and 3.86%) as the osmotic agent. The potassium concentration in current PD fluids is zero to aid control of potassium balance.

Lactate is used as a buffer instead of bicarbonate because bicarbonate and calcium may precipitate (to form calcium carbonate) during storage. With the advent of newer multichambered PD delivery systems, it is possible to replace lactate with bicarbonate and to make a number of other solution modifications that previously were not feasible. However, the high cost of a number of the newer, more physiologic fluid formulations should be borne in mind.

Electrolyte Concentration

In current PD fluids, the concentrations of sodium, chloride, calcium, and magnesium are selected to be close to the plasma (equilibrium) concentration. The removal of these ions across the peritoneum is therefore due to the low diffusion gradient, more or less completely dependent on convection. For every deciliter of fluid removed in a 4-hour dwell, approximately 10 mmol/l of sodium¹⁶ and 0.1 mmol/l of calcium are removed, provided plasma sodium and calcium concentrations are within the reference ranges.¹²

The frequent use of calcium-containing phosphate binders requires an understanding of calcium kinetics for various types of dialysis fluids to avoid hypercalcemia. The calcium concentration of current PD solutions is usually 1.25 to 1.75 mmol/l. However, because calcium, like sodium and magnesium, has a UF-dominated transport, 1.25 mmol/l may be considered appropriate only for 1.36% glucose to achieve a zero ("neutral") peritoneal calcium removal. To reach the same objective for 4% glucose, the dialysis fluid calcium would have to be increased to 2.3 mmol/l to prevent UF-driven calcium loss during a 4-hour dwell. With use of a three-compartment system for the PD bags, it would be possible to adapt the dialysis fluid calcium concentration either to obtain net zero peritoneal calcium transport across the peritoneum or to reach a preset calcium removal target for

each PD fluid glucose concentration used.¹⁷ However, in currently available PD solutions, calcium concentration is not variable as a function of glucose concentration; therefore, 1.25 mmol/l of calcium is recommended when patients use calcium-containing phosphate binders. However, net peritoneal calcium removal with a calcium level of 1.25 mmol/l can be achieved only by PD fluids containing 2.27% or 3.86% glucose.

The magnesium concentration commonly used in current PD solutions is 0.25 to 0.75 mmol/l. For 1.36% glucose, 0.25 mmol/l would be appropriate for zero magnesium transport during the dwell, whereas for higher dialysis fluid glucose concentrations, there will be net magnesium loss with this concentration.

Osmotic Agents

Glucose is the principal osmotic agent used for fluid removal (UF) in PD. Alternative commercially available osmotic agents are amino acids and icodextrin. Icodextrin is a polydispersed glucose polymer with an average molecular weight of 17 kd.¹⁸ However, because of the polydispersity of icodextrin, ~70% of the molecules have a molecular weight of 3 kd or less.¹¹ Icodextrin is available as a 7.5% solution with essentially the same electrolyte composition as glucose-based dialysates. The osmolality of the glucose polymer solution, unlike that of 1.36% glucose (osmolality = 350 mosmol/kg) dialysis fluid, is within the same range as or actually slightly lower than that of normal plasma. The presence of larger molecules in the icodextrin solution, compared with those in glucose-based solutions, improves the osmotic efficiency markedly across the small pores ($\sigma = 0.5$) and also reduces the dissipation of the osmotic gradient over time. This yields a sustained UF during 8 to 12 hours (Fig. 92.7A). Therefore, icodextrin is preferably used for long dwell exchanges, for example, overnight, and particularly for patients who tend to absorb glucose rapidly (fast transporters, see later).

Another alternative osmotic agent, which is commercially available, is a 1.1% amino acid mixture having the same osmolal-

ity as 1.36% glucose.¹⁹ According to some studies, regular use of this dialysate may increase certain nutritional indices, although there is also some evidence that amino acid solutions increase acidosis and raise plasma urea concentration. Both icodextrin-based and amino acid-based solutions may be used to reduce the glucose exposure of the peritoneal membrane and the total glucose load to the patient.

Until recently, conventional PD solutions have had a low pH and a high concentration of glucose degradation products (GDPs). GDPs are reactive carbonyl compounds that form during heat sterilization or storage of glucose-based solutions. GDPs are toxic to a variety of cells *in vitro* and also potentially toxic *in vivo*.²⁰ By the use of multicompartiment systems, it has been possible to compose new solutions with much lower concentrations of GDPs and a neutral pH and also to use bicarbonate or bicarbonate-lactate mixtures as buffer.²¹⁻²³ Solutions using bicarbonate or bicarbonate-lactate mixtures result in significantly less infusion pain and are as effective as lactate at correction of acidosis when they are used at the same total buffer ion concentration.²⁴ In prospective, randomized studies, these fluids have been associated with improvement in dialysate effluent markers of peritoneal membrane integrity, particularly cancer antigen 125 (CA-125), a measure of peritoneal mesothelial cell mass.²¹⁻²³ There have also been some indications of improved residual renal function in patients with PD solutions low in GDPs,²³ although this was not confirmed in a prospective randomized study.²⁵

Pyruvate is an alternative buffer to lactate (or bicarbonate) but is not yet clinically available. Finally, certain additives may help preserve the peritoneal membrane, such as *N*-acetylglucosamine, hyaluronic acid, citrate, and low-molecular-weight heparin. Low-molecular-weight heparin, 4500 IU in every morning bag daily for 3 months, increased UF by reduced glucose reabsorption during the dwell.²⁶ This may be due to reduction of the initial vasodilation that regularly occurs with intraperitoneal instillation of glucose-based PD solutions.²⁶ Hyaluronic acid seems to reduce the reabsorption of fluid that occurs in the late

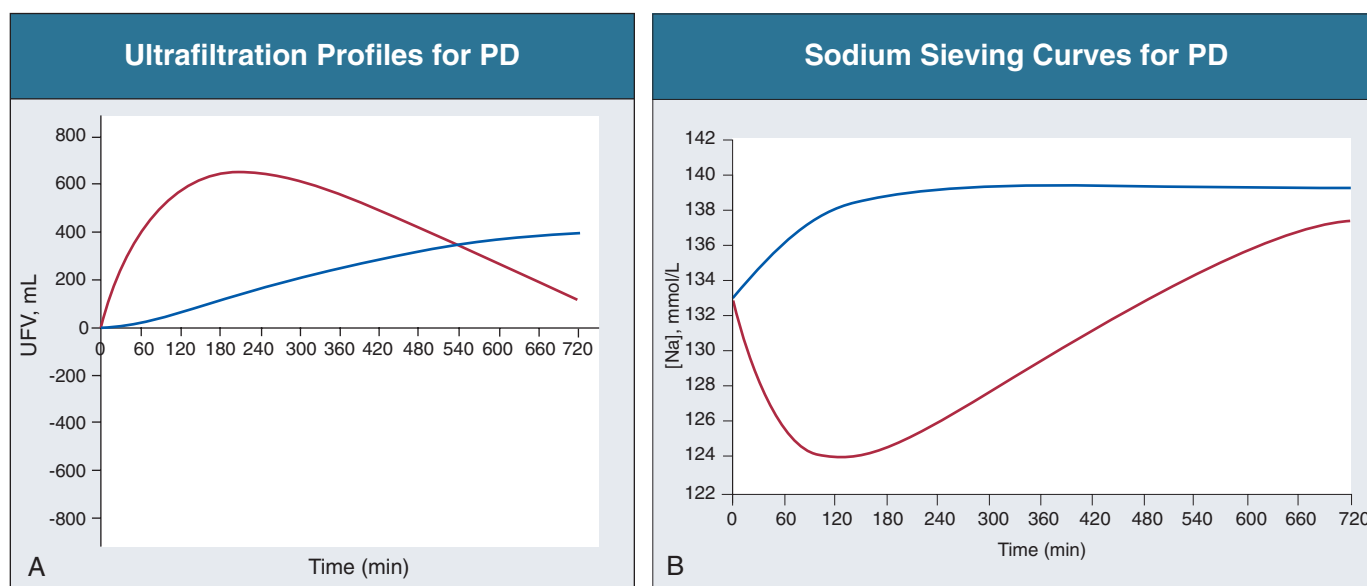

Figure 92.7 **A, Ultrafiltration profiles for PD.** UF profile for 7.5% icodextrin (blue line), computer simulated according to the three-pore model in an average patient who is not naive to icodextrin, in comparison with the computer-simulated UF curve for 3.86% (red line) glucose (see Fig. 92.3). **B, Sodium sieving curves for PD.** Sodium sieving curves for 7.5% icodextrin (blue line) and 3.86% glucose (red line) (see Fig. 92.3). (A from reference 11.)

phase of the dwell, possibly by producing a “filter cake” at the peritoneal surface.²⁷ None of the additives (*N*-acetylglucosamine, hyaluronic acid, or low-molecular-weight heparin) or buffers (pyruvate, citrate) can yet be recommended in routine clinical practice, and further trial data are awaited.

ASSESSMENTS OF PERITONEAL SOLUTE TRANSPORT AND ULTRAFILTRATION

Small Solute Removal

The net removal of solutes and fluid during PD, in excess of residual renal excretion, can be measured by evaluating the drained dialysate. For this purpose, the concentrations of urea and creatinine are measured in dialysate and plasma. The dialysate to plasma concentration ratios (D/P) of either of these solutes multiplied by the daily drain volume gives the 24-hour clearance. Weekly creatinine and urea clearances are obtained by multiplying these figures by 7. For comparison between patients, creatinine clearances are conventionally related to body standard surface area (1.73 m²); urea clearance (mostly for comparison with HD) is expressed as Kt/V (where Kt is the weekly clearance and V the volume of distribution of urea). In PD, routine assessment of V is imprecise, in contrast to the situation in HD, in which V can be mathematically derived directly from urea kinetics. V should preferably be determined by direct techniques, such as from the dilution of isotopic water (total body water); in practice, however, V is usually approximated from standard tables using body weight and height as anthropometric parameters together with gender.²⁸ The Kt/V concept in conjunction with PD is open to criticism, mostly because of the uncertainty of determining a correct value for V .

Large Solute Removal

To gain more insight into peritoneal transport, the clearance of larger solutes, such as β_2 -microglobulin, as well as of markers for transport across the large pores, such as albumin, immunoglobulins, and α_2 -macroglobulin, can be measured. Whereas many centers assess the daily peritoneal removal of total protein or albumin, measurements of most other solutes are not made in routine clinical practice.

Ultrafiltration

UF can be assessed with a 24-hour collection. Even if it is done accurately, there is a considerable dwell-to-dwell and day-to-day variability in UF, depending on drainage conditions, posture, and varying levels of residual (sump) intraperitoneal volume. Reasonably accurate estimations of daily UF volume can be obtained by averaging collections of all fluid during a period of several days. In clinical practice, the patient's own daily dialysis records should also be examined with respect to dwell-to-dwell UF volumes and the number of hypertonic bags used per day. UF volume can also be determined by the so-called peritoneal equilibration test as described later. For a 3.86% glucose dwell, a UF volume of less than 400 ml will indicate insufficient UF, that is, UF failure. In a routine 2.27% glucose peritoneal equilibration test (see later), less than 200 ml of UF in 4 hours signals UF failure. More accurate determination of intraperitoneal volume can be achieved as a function of time with use of an intraperitoneal volume marker, such as ¹²⁵I-labeled human serum albumin or dextran 70 (while correcting for marker clearance

from the peritoneal fluid). With such marker techniques, more precise UF volume estimations can be made, which is a prerequisite for accurate estimations of true membrane parameters in terms of permeability–surface area products (PS or MTAC) for small solutes or clearance for macromolecules.

Peritoneal Membrane Function

Peritoneal Equilibration Test

The peritoneal equilibration test (PET) yields approximate estimations of the rate of peritoneal transport of small solutes and of UF capacity.²⁹ The rate of small solute transport is dependent on the effective peritoneal surface area, which is essentially dependent on the number of effectively perfused capillaries available for exchange (and the blood flow). The volume ultrafiltrated in 4 hours is a function of the so-called osmotic conductance to glucose (the peritoneal UF coefficient times the reflection coefficient for glucose) as well as the rate of dissipation of the glucose osmotic gradient (= rate of small solute transport). In general, when the rate of glucose disappearance is high (for fast transporters, see later), UF volume is low. The PET procedure is summarized in Figure 92.8. After an overnight dwell (8 to 12 hours), the dialysate fluid is drained, and a 2-liter 2.27% glucose bag is infused during 10 minutes with the patient in the supine position (rolling from side to side every 2 minutes). At 10 minutes (after start), that is, at completion of the infusion, 200 ml is drained into the drainage bag and mixed, and a zero time dialysate sample is taken. At the end of the 4-hour dwell period, dialysate is drained out and measured. The net volume is noted. Concentrations of glucose and creatinine in the outflow and plasma are measured, as is the concentration of glucose in the zero sample. The results are expressed as the ratio of dialysate to plasma (D/P) solute concentration and as the ratio of glucose concentration at 4 hours to dialysate glucose concentration at time zero (D/D₀). The higher the D/P ratio is for creatinine, the faster the rate of transport for small solutes. According to D/P ratios for creatinine or D/D₀ for glucose, patients can be described as slow, slow average, fast average, and fast transporters (Fig. 92.9). However, D/P measurements give only an approximate estimation of small solute transport rate. An increased D/P-creatinine is usually accompanied by a lower UF volume, but a lower UF volume will *per se* automatically (due to less dilution) tend to increase the D/P.

Peritoneal Equilibration Test
1. The night bag (8–12 hours) must be 1.36% or 2.27% glucose, drained for 20 minutes with patient sitting.
2. 2 liters (warm) 2.27% fluid instilled for 10 minutes with the patient supine and rolling from side to side every 2 minutes.
3. Exactly at 10 minutes after start of the infusion, 200 ml is drained into the bag. Draw 5 ml (discard); 5 ml taken for creatinine and glucose determination.
4. After 2 hours, new samples collected as under 3.
5. After 4 hours (exactly) drainage during 20 minutes. Note total bag weight. Subtract empty bag weight. Take samples (after mixing) for creatinine and glucose.
6. The glucose at 4 hours to dialysate glucose at time zero for glucose and dialysate to plasma ratio for creatinine are D/D ₀ plotted versus time in a graph demonstrated in Figure 92.9. The drained volume is noted (D/P-creatinine)

Figure 92.8 Peritoneal equilibration test.

Figure 92.9 Interpretation of the peritoneal equilibration test. Changes in solute concentration allow classification into different transport types. (Modified from reference 29.)

Standard Permeability Analysis and the Fast-Fast Peritoneal Equilibration Test

In the standard permeability analysis (SPA), a 3.86% glucose bag is instilled, but the test is otherwise performed like the PET.³⁰ After a dwell time of 1 hour, a dialysate sample is taken and the sodium concentration is compared with that of the zero (time) value. This is done to assess the degree of sodium sieving and hence to obtain a measure of aquaporin-mediated water flow.³¹ In SPA, UF volume below 400 ml at 4 hours suggests UF failure. A variant of SPA has been suggested with complete drainage of a 3.86% glucose bag at 1 hour and measurement of the total drained volume.³² By such a technique, it is theoretically possible to assess the fraction of “free” water transport (across AQP1) in the early phase of the dwell when sodium diffusion is negligible from the 1-hour drained volume. First, the peritoneal clearance of sodium during 1 hour (i.e., the mass of sodium drained minus that instilled divided by the average sodium concentration in plasma) is calculated. The peritoneal clearance of sodium approximately equals the peritoneal small solute clearance of fluid (water) during the first hour of the dwell. This value is then subtracted from total UF volume. Thereby, a surprisingly accurate estimate of the free (aquaporin-mediated) water transport during the first 60 minutes is obtained, even without the application of a correction algorithm.³³ The apparent fraction of free water transport and the osmotic conductance may decline in long-term patients with UF failure, usually combined with increases in D/P-creatinine and a decline in D/D₀-glucose.³⁴

Residual Renal Function

In PD, residual renal function is of considerable importance for patient and technique survival. Residual renal function is better preserved over treatment time in PD than in HD.³⁵ Residual renal function can be assessed by collecting all urine during a day and by assessing the urine concentrations of urea and creatinine and total urine volume. Because renal creatinine clearance, due to tubular secretion, yields an overestimate of the glomerular filtration rate (GFR) by 1 to 2 ml/min when GFR is 10 ml/min or less, and renal urea clearance yields an underestimate of GFR by 1 to 2 ml/min in the same interval of reduced GFR, a good estimate of actual GFR can be calculated as the average of renal

Criteria for Peritoneal Dialysis Adequacy

Clinical	The patient feels well and has a stable lean body mass No symptoms of anorexia, asthenia, nausea, emesis, insomnia Stable nerve conduction velocity
Small solute clearance	Weekly Kt/V urea >1.7 (renal + peritoneal) Weekly creatinine clearance >50 l/1.73 m ²
Large solute clearance	Albumin clearance <0.15 ml/min
Fluid balance	No edema No hypertension No postural hypotension
Electrolyte balance	Serum potassium <5 mmol/l
Acid-base balance	Serum bicarbonate >24 mmol/l
Nutrition	Daily protein intake ≥1.2 g/kg Caloric intake >35 kcal/kg/day Serum albumin >35 g/l Body mass index 20–30 kg/m ² Stable midarm muscle circumference

Figure 92.10 Criteria for peritoneal dialysis adequacy.

creatinine clearance and urea clearance. However, if the daily urine volume is less than 200 ml, residual renal function will be too small to be measured accurately.

ADEQUACY

An important measure of dialysis adequacy is the general clinical state of the patient, as manifested by a good nutritional status (maintained muscle mass) and the absence of anemia, edema, hypertension, electrolyte and acid-based disturbances, neurologic symptoms, pruritus, and insomnia. Management of anemia and bone disease in ESRD patients is discussed in Chapters 79 and 81, respectively. Some criteria for PD adequacy are given in Figure 92.10.

Small Solute Clearance

There are few prospective randomized studies that define adequate PD. From a clinical point of view, it has been suggested

Typical PD Regimens Required to Achieve Adequate Solute Clearances				
Patient Body Surface Area (m ²)	Peritoneal Solute Transport Characteristics—D/P Creatinine at 4 Hours			
	Slow (<0.5)	Slow Average (0.5 to <0.65)	Fast Average (0.65–0.82)	Fast (>0.83)
<1.7	CAPD/APD	CAPD/APD+	APD+	APD
	10–12.5 liters	10–12.5 liters	10–12.5 liters	10–12.5 liters
1.7–2.0	CAPD+/APD	APD+	APD+	APD+
	12.5–15 liters	12.5–15 liters	12.5–15 liters	12.5–15 liters
>2.0	CAPD+, HD	APD+	APD+	APD+
		15–20 liters	15–20 liters	15–20 liters

Figure 92.11 Peritoneal dialysis regimens. Typical peritoneal dialysis regimens required to achieve adequate solute clearance according to patient size and membrane characteristics in anuric patients. The total volume of dialysate fluid required increases with body size, using 2.5- or even 3.0-liter exchanges. As solute transport increases, the use of automated peritoneal dialysis (APD) with shorter overnight exchanges is favored over continuous ambulatory peritoneal dialysis (CAPD). Both CAPD and APD may have to be augmented with an additional exchange (denoted by +); this is given by way of an additional afternoon exchange in CAPD patients or by employing an exchange device that delivers a single additional exchange at night. HD, hemodialysis. *The use of glucose polymer (icodextrin) solution for the long exchange will enhance both solute clearance and ultrafiltration.

that a weekly Kt/V above 1.7 and a weekly creatinine clearance above 50 l/1.73 m² would be minimally adequate for patients on CAPD. This represents only approximately 50% to 60% of the urea and creatinine clearance considered adequate in HD patients. In a large prospective study in the United States and Canada, the CANUSA study, the outcome for a cohort of 680 patients starting CAPD was studied with an average follow-up of 2 years.³⁶ In the CANUSA study, patients who maintained a high Kt/V or creatinine clearance over time did better than those who did not. An increase of 0.1 unit of Kt/V (peritoneal and renal) per week was associated with a 5% decrease in relative risk of death, and an increase of 5 l/1.73 m² of creatinine clearance per week (peritoneal and renal) was associated with a 7% decrease in the relative risk of death. Further analysis of the CANUSA study indicated that the survival advantage of patients with higher total small solute clearance was entirely attributed to the residual renal function. For each increase of 250 ml of urine output per day, there was a 36% decrease in the relative risk of death. In the ADEMEX study,³⁷ a large randomized controlled clinical trial designed to test the value of increasing peritoneal small solute clearance in a Mexican PD cohort, there was no obvious survival advantage of increasing the peritoneal clearance to obtain a total creatinine clearance above 60 l/1.73 m² compared with less than 50 l/1.73 m².

From these studies, it seems that renal clearance and peritoneal clearance are not mutually comparable. High residual renal function is of greater survival advantage than high peritoneal solute transport capacity. The mere fact that the survival of PD patients is equal to or supersedes that of HD patients during the first 2 to 3 years of dialysis (see later), despite the fact that PD provides ~50% of the total Kt/V of HD, indicates that the benefit of PD goes beyond the clearance of small solutes. In a European multicenter study of APD, the EAPOS study, small solute clearance did not correlate with survival in anuric patients.³⁸ On the contrary, total volume removal and hydration state were important factors. Still, there is reasonably good evidence that a weekly Kt/V above 1.7 and a weekly creatinine clearance above 50 l/1.73 m² are adequacy targets that should be reached and maintained in a majority of patients. As residual renal function declines, attempts should be made to increase the dose of dialysis,

either by increasing the exchange volumes or by prescribing more frequent exchanges.

The concept of Kt/V , a kinetic parameter obtained from HD practice, is somewhat questionable in PD. Theoretically, body surface area would be superior to urea distribution volume to normalize urea clearance. Furthermore, the long-term PD patient is often overhydrated or has an increased fat mass, which makes the estimation of V cumbersome.³⁹ A patient with a high solute transport will achieve peritoneal creatinine clearance targets rather easily, whereas obese individuals may have difficulties in reaching an adequate Kt/V_{urea} .

Commercially available computer programs* can predict urea and creatinine clearances and peritoneal UF performance and provide suggestions for treatment options based on drained volumes and on plasma and dialysate creatinine and urea values. These parameters are often obtained by PET or standardized schedules for specified dwell exchanges. Some of the programs yield an estimate of peritoneal albumin clearance, which to a great extent is dependent on the filtration occurring across large pores, being increased in “inflammation.” Recommended dialysis schedules based on the categorization of the PET are given in Figure 92.11.

Fluid Balance

As in all types of renal replacement therapy, long-term maintenance of adequate fluid and electrolyte balance is of crucial importance for the survival of patients on PD. As already mentioned, the outcome of PD is directly related to residual renal function, particularly a high urine output. Furthermore, patients with fast transport in the PET (a more rapid absorption of glucose and a more rapid loss of the osmotic gradient) have a reduced technique survival. It seems evident that after 2 or 3 years of PD, when residual renal function is low, most patients on PD are fluid overloaded. It is likely that volume overload not only

aggravates hypertension but also leads to progression of left ventricular hypertrophy, often already present at the start of PD. However, during the first year of PD, there is often a fall in blood pressure and a reduced need for antihypertensive agents. Unfortunately, with time on PD, blood pressure usually rises and the number of antihypertensive drugs needed usually again increases.⁴⁰ Therefore, it is advisable to regularly assess fluid removal in the patients over time, at least every 6 months, either separately (using SPA) or in conjunction with PET measurements.

Management of Fluid Overload

As total urinary water (and sodium) excretion and peritoneal UF volume decline, it is advisable to instruct patients to restrict salt and water intake. In view of the difficulty in compliance with salt restriction, the use of PD solutions with lower sodium concentration has been advocated. Preliminary studies of low-sodium PD solutions have been very promising, reducing the need for blood pressure-lowering drugs to control hypertension⁴¹; however, low-sodium solutions are not yet commercially available. Loop diuretics such as furosemide (250 to 500 mg daily) can be used to maintain urine volumes but do not maintain renal clearance. If salt and water restriction and diuretics are not effective in maintaining UF, it can be enhanced by increasing the dialysis glucose concentration to 2.27% (or 3.86%). Patients with alterations in peritoneal membrane function appearing in the first few years of PD usually have an increased small solute transport combined with only a moderate increase in peritoneal UF capacity,³⁴ and there is an increased reabsorption of fluid in the late phase of the dwell. These patients can benefit from switching to APD and to the use of icodextrin for one of the daily exchanges. Randomized controlled trials using icodextrin for the long daytime dwell in APD have demonstrated an improved UF and a reduced extracellular fluid volume.⁴² Patients who have been on PD for several years may have a reduced UF capacity (reduced osmotic conductance to glucose).³⁴ These patients would theoretically benefit less from switching to icodextrin because of the reduced UF capacity.

Nutrition

During their first year of treatment, CAPD patients typically have evidence of net anabolism; the average weight gain may exceed 5 kg without any clinical signs of fluid overload. Contributing to this weight gain is the peritoneal glucose reabsorption (on average, 100 to 150 g daily), which adds 400 to 600 kcal of energy intake daily. As residual renal function declines, the nutritional and metabolic abnormalities in CAPD become increasingly manifested, with reductions in lean body mass. The main cause of protein-energy malnutrition and wasting, apart from poor food intake, is the impaired metabolism of protein and energy in uremia. Despite glucose absorption, many patients on long-term CAPD have signs of energy malnutrition, a major component of the uremic wasting syndrome. Contributing factors are low-grade inflammation associated with carbonyl and oxidative stress and accelerated atherosclerosis, the so-called malnutrition-inflammation-atherosclerosis syndrome.⁴³ It is important for CAPD patients to be prescribed an adequate amount of protein (>1.2 g of protein per kilogram per day) and energy (total energy intake >35 kcal per kilogram per day) and a sufficient dose of dialysis, enabling the patient to ingest this diet. The daily losses of protein to the dialysate are not negligible but approximate 5 to 7 g daily, of which ~4 to 5 g is albumin. This actually compares to the losses occurring in nephrotic-

range proteinuria. The nutritional management of PD patients should include frequent assessments of their nutritional status, and if it is inadequate, referral for HD (or transplantation) should be considered. Nutrition in PD patients is discussed further in Chapter 83.

OUTCOME OF PERITONEAL DIALYSIS

Registry data¹ have indicated a lower risk of death in patients treated with PD during the first 2 years of treatment compared with those treated with HD, although overall, the mortality in PD compared with HD is not significantly different. Survival differences seem to vary substantially according to the underlying cause of ESRD, age, and baseline comorbidity. In a study based on U.S. Medicare registry data,⁴⁴ HD was associated with a higher risk of death among diabetic patients with no comorbidity and among younger patients (18 to 44 years), whereas PD was associated with a higher risk of death among older patients (45 to 64 years). In patients with mortality rates adjusted for comorbidity at start of dialysis, there were no differences between HD and PD among nondiabetic patients and among younger diabetic patients (18 to 44 years), but mortality was higher on PD for older diabetic patients with baseline comorbidity.

Complications of Peritoneal Dialysis

Simon J. Davies, John D. Williams

CHANGES IN PERITONEAL STRUCTURE AND FUNCTION

Loss of peritoneal function is a major factor leading to late treatment failure in peritoneal dialysis (PD).¹ Although the precise biologic mechanisms responsible for these changes are not fully understood, it is widely assumed that alterations in peritoneal function, a combination of an increased rate of small solute transport and loss of ultrafiltration (UF) capacity, are related to structural changes in the peritoneal membrane.² There is accumulating evidence that continuous exposure to dialysis solution components and repeated episodes of bacterial peritonitis (Fig. 93.1) are the main drivers of this process. Whereas the relationship between structure and function has not been fully defined, increased solute transport is likely to reflect a greater vascular surface area, which in turn causes reduced UF due to early loss of the osmotic gradient and enhanced fluid reabsorption (type 1 UF failure). There is also evidence of an additional mechanism by which membranes exhibit a reduced UF capacity for a given osmotic gradient (type 2 failure, reduced osmotic conductance) that might be explained by progressive fibrosis.

Studies that have quantified these changes within the submesothelial collagenous zone suggest a progressive increase in thickness with time on PD (Figs. 93.2 and 93.3). Changes within the peritoneal vascular bed have also been identified. These include progressive changes to the structure of small venules ranging from subtle thickening of the subendothelial matrix to complete obliteration of vessels (Fig. 93.4).³ In one study, the extent of these changes in a small group of patients correlated with the loss of ultrafiltration.⁴ Thus there is accumulating evidence that changes occur in both the interstitial and vascular compartments of the dialyzed peritoneal membrane.

Given that one of the likely drivers of membrane damage is the toxic profile of conventional dialysis solutions (low pH, lactate buffers, high concentration of glucose degradation products), new, more biocompatible solutions have been developed that variably correct these factors. Initial studies using these fluids indicated that dialysate effluent biomarkers thought to represent membrane integrity improve, with a reduction in circulating glucose degradation products.⁵⁻⁷ There is still little evidence that this translates into clinically relevant endpoints, in part because of the inherent difficulties in undertaking sufficiently powered randomized trials. There is suggestive evidence from some studies that residual renal function might be better

preserved, but these data are confounded by a concomitant reduction in peritoneal UF. Whereas these solutions are more biocompatible, to achieve adequate UF, it remains necessary to use high glucose concentrations that are unphysiologic and may still damage the membrane. When possible, excessive glucose exposure should be avoided to preserve the membrane.

REDUCED ULTRAFILTRATION AND ULTRAFILTRATION FAILURE

Recognizing the Problem

There is increasing evidence that reduced UF is associated with poor survival in PD.⁸⁻¹⁰ The cause and effect in this relationship are not clear because the studies are observational, but in the only study with a preset UF target (>750 ml/day), mortality was significantly worse in those patients who were identified as having reduced peritoneal UF capacity, resulting in daily UF consistently below this level.⁹ UF failure, often defined as less than 400 ml at 4 hours after a 3.86% exchange, is also associated with technique failure. This occurs in up to 31% of patients by 6 years of treatment.

Problems with UF should be suspected if patients have signs of fluid overload or are using excessive numbers of hypertonic exchanges and when the total fluid removal per day (urine plus dialysate) is less than 1 liter. It is important to check the actual drainage volumes by asking the patient to bring the bags to the unit and to remember to include the overfill flush volume in the calculation of net UF. In these circumstances, peritoneal membrane function tests should be performed to establish the solute transport rate and UF capacity of the membrane. If membrane function is normal and ultrafiltration adequate, it is likely that fluid or salt intake is excessive, and educational measures must be undertaken to correct this. Diabetics may require improved blood glucose control, which will be helped by reducing the glucose prescription and using icodextrin and amino acid solutions.¹¹ If the UF capacity is less than 200 ml (including overfill, otherwise zero net UF) by a routine peritoneal equilibration test (PET)¹² with 2.27% glucose or less than 400 ml by a modified standard permeability analysis (SPA)¹³ with 3.86% glucose, then treatment strategy is determined by transport status (4-hour dialysate to plasma creatinine ratio). It is recommended that patients undergo routine membrane function tests (PET or SPA) at 6 weeks after starting PD and then at least on an annual basis or when clinical problems with fluid management are manifested.

Management of Fast Solute Transport Ultrafiltration Failure (Dialysate to Creatinine Ratio >0.64 at 4 hours)

In observational studies, increased solute transport is consistently associated with increased mortality and technique failure, independent of age, gender, and comorbidity. In patients with fast transport, there is a more rapid absorption of glucose from the peritoneal cavity, which results in the early loss of the osmotic gradient, leading to reduced net UF and more rapid fluid reabsorption once the osmotic gradient has dissipated. Short dwell periods reduce the degree of fluid reabsorption, and a change to automated PD (APD) using several (typically four or five) short overnight cycles may improve the situation. If there is a significant urine output, a loop diuretic in high dose should be tried. Furosemide, 250 mg/day, has been shown in a randomized study

to maintain urine volume and sodium excretion without affecting clearances.¹⁴

For the long dwells, icodextrin, a glucose polymer that is iso-osmotic with plasma, can generate prolonged UF due to a sustained oncotic pressure gradient that also avoids fluid reabsorption. A number of randomized trials have shown that this prevents fluid reabsorption in the long dwell, resulting in a significant benefit compared with glucose 2.27% in fast transporters.¹⁵ It also improves the fluid status of these patients by reducing the extracellular fluid (EF) volume, usually by ~15%.¹⁶ When patients are started on icodextrin, care needs to be taken to avoid a rapid change in fluid status, typically seen in individuals in whom excessive fluid reabsorption was occurring, as this might result in a loss of residual renal function (RRF). When icodextrin has been used in long-term studies (e.g., in anuric patients using APD), fast peritoneal transport is no longer a risk factor for mortality and technique failure, and there is stable membrane function. Some patients, usually long term, will fail to achieve adequate UF despite these measures. These patients have usually acquired both fast solute transport and low osmotic conductance and have combined type 1 and type 2 UF failure (see later discussion).

Figure 93.1 Peritonitis. Scanning electron micrograph of the peritoneum from a patient receiving peritoneal dialysis (PD) who has peritonitis. The small round cells (arrows) are phagocytes, which are widely distributed among the mesothelial cells (M). (Magnification $\times 1800$.)

Management of Slow Transport Ultrafiltration Failure (Dialysate to Plasma Creatinine Ratio <0.64)

Although slow transport ultrafiltration failure is less common, its management is more difficult. It is essential to exclude any form of mechanical failure, such as an occult peritoneal cuff leak or an inguinal hernia, by contrast-enhanced computed tomography (CT). Once mechanical problems have been excluded, it is possible to determine whether the poor UF is due to a failure of UF or of excessive fluid reabsorption by determining whether sodium sieving is present. Typically, slow transport patients will have a sustained glucose gradient and will therefore exhibit sodium sieving (a decrease in the dialysate sodium concentration)

Figure 93.2 Peritoneal membrane thickening in peritoneal dialysis (PD).

The thickness of the submesothelial collagenous zone of the peritoneal membrane in normal individuals, in undialyzed uremics, in hemodialysis (HD), and in those who have received PD for different periods. Membrane thickness is significantly increased in all uremic and dialysis patients compared with normal. Membrane thickness increases significantly with duration of PD and is increased in PD patients as a group compared with HD patients.

Figure 93.3 Morphologic changes in the parietal peritoneal membrane. **A**, Normal. **B**, A patient who has been on peritoneal dialysis (PD) for 10 years. Note the marked thickening of the submesothelial compact zone (toluidine blue).

during the first 60 minutes of a 3.86% dwell. This occurs because of the convective transport of water through water exclusive pathways, now known to be capillary aquaporins. Lack of sieving indicates failure of the membrane to generate an ultrafiltrate. Patients with loss of sodium sieving will require regular hypertonic exchanges as well as strategies to preserve urine volume, such as use of diuretics¹⁴ or angiotensin-converting enzyme (ACE) inhibitors.¹⁷ For many of these patients, a planned transfer to hemodialysis (HD) once RRF is lost is the only practical outcome.

ENCAPSULATING PERITONEAL SCLEROSIS

A minority of patients on PD develop encapsulating peritoneal sclerosis, in which the bowel is enveloped in a thick cocoon of fibrous tissue, causing obstruction (Fig. 93.5). The current definition of this syndrome requires clinical features of obstructive bowel symptoms leading to weight loss and malnutrition (with or without features of systemic inflammation) combined with either typical features on imaging (CT scanning) or confirmation of fibrous cocooning at laparotomy. Although UF failure, especially when it is associated with loss of osmotic conductance (type 2), appears to be a risk factor, there are important differences

suggesting that this is at least in part a different pathologic process. It is predominantly a disease of visceral as opposed to parietal membrane, is usually associated with another risk factor or trigger (such as severe peritonitis or stopping of PD, including for transplantation), and frequently has a systemic inflammatory phase; biopsy material more often shows inflammation and, of note, fibrinous exudates.

The single most important risk factor for encapsulating peritoneal sclerosis is time on PD; at 5 years, the incidence is ~2% to 3%, whereas by 10 years, this rises to 6% to 20%.¹⁸ There is increasing evidence that the most successful treatment is surgery in the form of extensive adhesion lysis and excision of the peritoneum while avoiding enterotomy, especially when there are obstructive symptoms.¹⁹ Parenteral nutrition can be used, mainly as a preparation for surgery but occasionally as a long-term solution. In about 50% of cases, symptoms are less severe and gradually resolve. There appears to be little role for preemptive screening by CT scanning, but this is helpful in diagnosis. Most commonly, it develops after transfer from PD to either HD or transplantation; but if it develops on PD, the consensus is that PD should be stopped to avoid continued exposure to nonphysiologic dialysis solutions. Other strategies, such as continued irrigation, dual-modality treatment with PD and HD, and use of

Figure 93.5 Encapsulating peritoneal sclerosis. Abdominal CT scan of a patient with encapsulating peritoneal sclerosis showing extensive peritoneal thickening.

antifibrotic drugs such as tamoxifen, are practiced, but an evidence base is lacking.

CATHETER MALFUNCTION

Inflow Failure

A 2-liter bag of dialysate should take 15 minutes or less to run into the peritoneal cavity. If inflow is significantly slowed or even stopped completely, mechanical causes should be suspected. After it is checked that the tubing and catheter are not kinked, that all clamps or rollers are open to the inflow position, and that any frangible seal is fully broken, the catheter should be flushed vigorously with 20 ml of heparinized saline. If the catheter is cleared, then heparin should be added (500 U/l) to the next few cycles because the cause of the blockage is often a fibrin plug. Should the catheter remain blocked, a plain abdominal radiograph is required. If this shows that the catheter is in a satisfactory position in the pelvis, an attempt to restore patency should be made with urokinase. Urokinase (25,000 U in 2 ml of saline) is infused into the lumen of the catheter and left *in situ* for 2 to 4 hours. The catheter is then flushed. If inflow is restored, heparin should be added to the dialysate for the next few cycles. Should this procedure not be successful but fibrin is still thought to be the cause, an endoscopy brush may sometimes prove successful in unblocking the catheter.

If the radiograph shows the catheter to be malpositioned (Fig. 93.6), an attempt should be made to reposition the catheter tip into the pelvis. This can be done by use of a sterile semirigid rod, shaped into a curve and slid down the lumen of the catheter under radiographic screening control. This technique is not practical when the catheter has a swan neck configuration. Alternatively, the catheter can be repositioned at laparotomy or peritoneoscopy. Sometimes the catheter becomes wrapped in

Figure 93.6 Catheter malposition. Plain radiograph of the abdomen with curled catheter (arrows) misplaced in the upper left abdomen.

omentum, suggested usually by complete inflow and outflow failure. This requires a partial omentectomy or an omental hitch, a surgical procedure in which the omentum is temporarily held away from the catheter by a dissolvable suture.

Outflow Failure

The most common reason for outflow failure is constipation, although causes of inflow failure discussed previously should also be considered. Loading of the bowel with fecal material is often obvious on a plain radiograph, but treatment for constipation should be initiated without recourse to this investigation as it is so common. Constipation should be treated with oral laxatives or an enema. Subsequently, bowel action should be kept regular by increasing the fiber in the diet and, if necessary, the addition of a mild laxative such as lactulose or senna. Slow outflow can be a problem in APD patients, resulting in excessive machine alarms. This is best dealt with by switching to tidal APD and using a relatively large residual volume (>50% of the fill volume).

Fibrin in the Dialysate

During peritonitis, fibrin in the dialysate is common. If fibrin causes restriction to dialysate flow, heparin (500 U/l) should be added to each bag. A small number of patients have fibrin formation in the absence of peritonitis. Immediately on drainage, the bag may appear cloudy, but on standing, the fibrin will aggregate. The first time this happens, a sample must be sent to the microbiology laboratory to exclude infection. If this proves negative, the patient can be reassured. If catheter plugging occurs subsequently, regular use of heparin is recommended.

FLUID LEAKS

External Leaks

On occasion, fluid may leak from the exit site or even the incision used to insert the catheter into the peritoneal cavity. This is usually a problem that occurs early, particularly if dialysis is started soon after catheter insertion. Whenever possible, elective insertion of the catheter should be performed at least 10 days before dialysis is required to avoid early leaks. Catheters can be used immediately in the case of acute PD start by using APD, low fill volumes, and bed rest. In addition, the use of the

paramedian approach for the peritoneal entry site is thought to minimize the chances of this complication. If a leak occurs, PD should be withheld for as long as possible. If dialysis is necessary, APD can be used overnight with a dry day for at least 10 days.

Internal Leaks

Isolated edema of the abdominal wall suggests an internal leak from the peritoneal cavity, either spontaneously or in association with a surgical hernia. In contrast, genital edema suggests an inguinal hernia or patent processus vaginalis. On occasion, both can be present. The site of the leak can be visualized by CT scanning after intraperitoneal instillation of contrast material. It may be necessary for the patient to stand or to perform other maneuvers to increase intra-abdominal pressure before the leak is demonstrated (Fig. 93.7A). An alternative diagnostic test is to perform scintigraphy after injection of a compound such as technetium Tc 99m diethylenetriaminepentaacetic acid (^{99m}Tc -DTPA; Fig. 93.7B). A surgical repair will be required if a major leak is visualized and should always be considered in association with a hernia. Most leaks, however, will heal after resting or with APD, using dry days, or temporary HD.

Hydrothorax

A pleural effusion can occur with generalized fluid overload or local lung disease, but it is occasionally caused by a leakage of dialysate through the diaphragm (Fig. 93.8). This more commonly occurs on the right side. A leak is most simply confirmed by aspirating a sample of the effusion and demonstrating that its glucose concentration is higher than the patient's blood glucose concentration. Initially, conservative measures should be tried. These include stopping PD, aspirating the effusion to dryness, and leaving the abdomen dry for 2 weeks (using HD, if necessary). This regimen is effective in a number of patients. If the condition recurs, pleurodesis can be tried; various agents have been advocated, but introduction of tetracycline or talc under direct vision with video-thoracoscopy is the best described.

PAIN RELATED TO PERITONEAL DIALYSIS

Inflow Pain

Soon after starting PD, patients may experience pain during fluid inflow. This is particularly likely to occur if dialysis begins immediately or within a few days of catheter insertion. Slowing the rate of fluid inflow will often reduce the symptoms, and peritonitis should be excluded and treated. A small number of individuals have persistent inflow pain. Randomized controlled trials have demonstrated that bicarbonate/lactate-buffered dialysis fluids at physiologic pH are associated with a dramatic improvement in infusion pain in such individuals.²⁰

Backache

Backache occurs in a minority of PD patients; the presence of a large volume of fluid in the abdomen distorts the normal posture, exacerbating any tendency to lordosis of the spine. Patients with preexisting back problems are most likely to have an exacerbation of their backache, although not all will be affected. It is important to investigate the symptom to exclude treatable or serious disease. Adjusting the dialysis regimen to

Figure 93.7 Inguinal hernia during peritoneal dialysis. **A**, CT scan after intraperitoneal injection of contrast material in a male patient showing dialysate flowing into a right inguinal hernia. **B**, Peritoneal scintigram of a male patient on peritoneal dialysis showing bilateral inguinal hernias. The left hernia extends into the scrotum; the right hernia is less extensive. (**A** from reference 21.)

reduce the daytime volume or leaving the abdomen empty of fluid during the day can help symptoms, provided dialysis treatment is not compromised.

Outflow Pain

Some patients have discomfort or even pain when the fluid runs out. This emptying sensation is abolished when the next cycle

Figure 93.8 Hydrothorax in peritoneal dialysis. Chest radiograph showing a right-sided pleural effusion with partial collapse of the right lung caused by a diaphragmatic leak.

runs in. This commonly occurs during peritonitis but may be experienced in the absence of infection during the first few weeks of PD. Switching to tidal APD will often solve this problem. Tidal therapy enables a prescribed amount of fluid to remain in the peritoneal cavity throughout treatment. If this is set to between 50% and 80% of the inflow volume, pain and drainage alarms are often prevented.

BLEEDING

Exit Site

The exit site can be a source of blood loss at any time while a peritoneal catheter is in place. A common cause is the removal of a crust before natural separation has occurred. The bleeding almost invariably stops with local pressure, but a new raw area that is liable to become infected remains. Regular cleansing of the exit site with povidone-iodine will reduce the chances of this complication. Patients must be instructed not to pull off the crust but to await its natural separation. Severe infection of the exit site may, on occasion, be accompanied by secondary hemorrhage. This will usually respond to firm pressure. The subsequent management is the same as for any exit site infection.

Blood-Stained Dialysate

Blood-stained dialysate is uncommon. It is rarely serious but causes considerable alarm to the patient. There is sometimes a clear history of trauma to the abdomen or of unexpected strain. A few female patients relate the episode to their time of ovulation or menstruation. The treatment is to flush the abdomen with a few cycles of dialysate containing heparin (500 U/l) to minimize the chances of clotting in the catheter. The problem usually resolves spontaneously and often is visible only in one outflow. It is unusual for the blood-stained dialysate to be associated with infection, although it is wise to have the fluid cultured. Routine use of antibiotics is not necessary. Blood-stained

dialysate can be a presenting feature of encapsulating peritoneal sclerosis, so if this is suspected clinically, a CT scan or laparoscopy and biopsy should be performed.

NUTRITIONAL PROBLEMS

Malnutrition

Cross-sectional surveys of patients receiving PD show that about 40% have malnutrition and 8% have severe protein-calorie depletion. Malnutrition is an adverse risk factor for morbidity and mortality of patients on PD; this poor nutrition is multifactorial. The assessment and management of malnutrition are discussed further in Chapter 83. It has been suggested that ideally, patients should consume daily at least 1.2 to 1.3 g of protein per kilogram of body weight. In practice, many subjects take only about 0.8 g/kg per day and seem to be nutritionally stable. It is likely that they have achieved a steady state but with a lower total body nitrogen or lean body mass.

Patients on continuous ambulatory peritoneal dialysis (CAPD) have abnormal eating behavior with smaller meals, slow eating, and impaired gastric emptying compared with normal subjects. The full peritoneal cavity may produce easy satiety, and some patients complain of feeling bloated. However, studies have shown that there is no actual difference in food consumption with or without dialysate in the abdomen.

One obvious contributing factor is protein loss through the peritoneum, which averages 8 g/day but can be as high as 20 g/day. It increases considerably during peritonitis. Patients with fast solute transport also have high peritoneal protein losses, in particular albumin. In both cases, the protein loss is a reflection of a larger effective peritoneal surface area. The ensuing hypoalbuminemia complicates poor UF and exacerbates the extracellular fluid (ECF) expansion in these patients.

Acid-Base Status

Another important influence on nutrition is the acid-base status of the patient. Correction of acidosis reduces protein catabolism. One study compared the use of 35 mmol/l lactate dialysate with fluid containing 40 mmol/l lactate.²⁵ After 1 year, the group receiving the higher lactate concentration had increased serum bicarbonate levels and, more important, had gained more weight with a greater increase in midarm muscle circumference. This implies that protein anabolism had taken place as the result of better acid-base correction. Correction of malnutrition is not easy. Clearly, patients should be encouraged to increase protein and calorie intake. Food supplements are of particular value during intercurrent illness. One report suggested that the regular use of a calorie supplement was associated with increased total body nitrogen after several months, but this remains to be confirmed. Correction of acidosis is best achieved by use of dialysate with higher levels of potential buffer,²² but if necessary, oral bicarbonate may be added.

Amino acid-based dialysate improves nitrogen balance in malnourished patients, but the long-term benefits are still unclear.²³ One bag per day is usually recommended during the daytime when calories are being consumed to promote anabolism and to avoid the risk of the absorbed amino acids being used for energy production. Earlier reports noted a tendency to acidosis with this type of dialysate, which would negate any beneficial effect. Close observation of the serum bicarbonate is necessary, with supplementation as required.

Lipids and Obesity

The use of glucose-based hyperosmolar solutions for PD results in a significant increase in the glucose load experienced by the patient. A number of reports have measured the daily glucose absorption, which is estimated to be 100 and 200 g/day, producing 400 to 800 kcal. The resultant metabolic effect is a tendency for patients on CAPD to develop central obesity, hyperglycemia, and hyperinsulinemia; they may even develop frank diabetes. These problems can be reduced by use of icodextrin in place of glucose.²² Serum triglycerides and cholesterol increase during the first year on CAPD, with increases in very-low-density and low-density lipoproteins. The greater the degree of hyperlipidemia at the start of therapy, the worse will be the changes with time on CAPD. In addition, there is some evidence that lipoprotein(a) levels may increase with time on CAPD (although this has not been consistently confirmed). Proatherogenic lipid levels are more common in patients on CAPD than in patients on HD. A number of studies have demonstrated the effectiveness of cholesterol-lowering agents in patients on CAPD. Statins are of proven efficacy in reducing total cholesterol and low-density lipoprotein cholesterol while increasing high-density lipoprotein cholesterol. However, the long-term effects of such intervention on cardiovascular (CV) morbidity and mortality in CAPD patients have yet to be established.

There is no evidence to suggest that PD should be avoided in obese patients despite these concerns. The survival advantage seen in HD associated with a higher body mass index is not seen.²⁴

INFECTIOUS COMPLICATIONS

Peritonitis

Although the introduction of disconnect delivery systems has reduced the incidence of peritonitis, it remains one of the most important complications of PD and is a major cause of treatment failure. Guidelines for the diagnosis and management of PD peritonitis are published by the International Society for Peritoneal Dialysis (ISPD; www.ispd.org).²⁵ The spectrum of peritonitis and its management in children have also recently been described in detail.²⁶

Diagnosis of Peritonitis

The diagnosis of peritonitis should be suspected in any patient who develops a cloudy bag when PD fluid is drained or abdominal pain. Fever may also be present but is not a universal feature. Patients should be advised to contact their dialysis unit immediately if they observe a cloudy bag or develop persistent abdominal pain. Samples of the dialysate should be taken for cell count and microbiologic examination. The diagnosis is confirmed by finding more than 100 white blood cells/mm³ (1×10^7 cells/l). A Gram stain of the spun deposit should also be performed to help identify the type of causative organism, although initial treatment will usually be empiric pending culture and sensitivity results. Various culture techniques have been proposed, but white cell lysis and inoculation into blood culture media is often helpful in increasing the yield of a positive growth.

The dialysate leukocyte count will be affected by dwell length, and this needs to be taken into account in APD patients. In short dwells, the count will be lower, and under these circumstances, if the proportion of cells that are neutrophils exceeds 50%, empiric treatment of peritonitis should be commenced.

Antibiotic Regimens for Bacterial Peritoneal Dialysis Peritonitis	
Culture	Antibiotic
Enterococci (including vancomycin-resistant enterococci)	Ampicillin
<i>Staphylococcus aureus</i> * Methicillin resistant*	Cephalosporin/floxacin (flucloxacillin) Vancomycin
Other gram-positive organism†	Cephalosporin/floxacin
Gram-negative organisms (including <i>Pseudomonas</i> species)*	Cefazolin, quinolone, or aminoglycoside‡, depending on sensitivities and residual renal function
Multiple/anaerobic organisms*	Metronidazole ± laparotomy
Culture negative	Continue empirical treatment

Figure 93.9 Antibiotic regimens for bacterial peritoneal dialysis (PD) peritonitis. Suggested antibiotic regimens when dialysate fluid culture is available. Except for culture-negative episodes, empiric treatment is stopped once the sensitivities are known. All antibiotic regimens should be developed in consultation with local microbiology practices. *Three-week treatment. †Two-week treatment. ‡Avoid unnecessary use if there is residual function.

Conversely, if the patient has had a dry abdomen during the day, the initial drain on connection may be cloudy. This will clear within one or two cycles, however, and the majority of the cells found will be mononuclear leukocytes.

Treatment of Peritonitis

The empiric treatment of peritonitis will vary according to center and should be developed in close collaboration with the local microbiology service, taking into account sensitivity patterns and infection control policy. Initial regimens must cover both gram-positive and gram-negative organisms; in the latest ISPD guidelines, examples of appropriate antibiotics include vancomycin, cephalosporins, and aminoglycosides.²⁵ Dosing regimens will depend on whether the patient is on CAPD or APD. For CAPD, the antibiotic is administered as a loading dose in the first bag and then as a maintenance dose in subsequent bags. Although it was customary to transfer APD patients to CAPD for the purpose of treating peritonitis, this is no longer necessary. APD patients are now given large loading doses into dialysis fluid with a minimum 6-hour dwell (e.g., vancomycin 30 mg/kg) and then are given further doses every 3 to 5 days according to checked blood levels. Once the culture result is available, the regimen should be modified accordingly (Fig. 93.9). If the organism is methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin will continue as part of the regimen.

If the culture is negative, empiric therapy should be continued for 2 weeks, assuming there is a clinical response. If a gram-negative organism is identified, the subsequent management will depend on the sensitivity (Fig. 93.10). The isolation of multiple organisms including anaerobes strongly suggests major bowel disease. Metronidazole should be added to the regimen and consideration given to surgical intervention.

A wide variety of antibiotics other than those cited have been used with success. In particular, a commonly used strategy is to include an oral quinolone, such as ciprofloxacin, instead of an aminoglycoside because ototoxicity and loss of residual renal function may occur with aminoglycosides. Current recommendations are that for gram-positive organisms, therapy should be

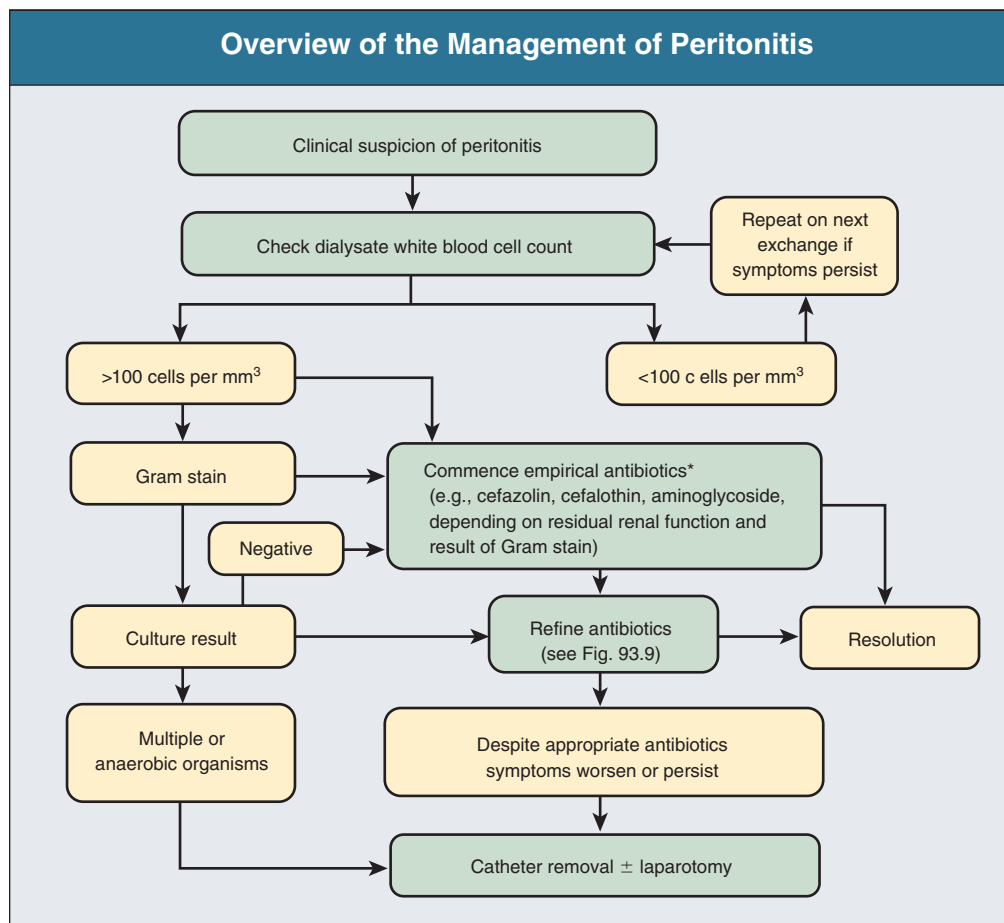

Figure 93.10 Overview of the management of peritonitis.

for 14 days except in the case of *S. aureus*, for which 21 days is suggested. For culture-negative episodes, 14 days of therapy should suffice. The same is true in the case of single-organism gram-negative peritonitis. For *Pseudomonas*, *Xanthomonas* species, or multiple organisms, 21 days is recommended.

Many patients can be treated successfully as outpatients. It is extremely important, however, that they are followed up either in the clinic or by telephone. In most cases, clinical resolution, as judged by the clearing of the bags, starts within 48 hours. If there is no improvement within 96 hours despite use of the correct antibiotic, as judged by sensitivity tests, the fluid must be retested by cell count, Gram stain, and culture. In the case of a persistent *S. aureus* infection, an underlying tunnel infection should be excluded. In all other situations in which there is a failure to improve, serious consideration should be given to removal of the catheter. In addition, the possibility of intra-abdominal or gynecologic disease or the presence of unusual organisms such as mycobacteria should be considered. Under these circumstances, a mini-laparotomy should be performed to exclude intra-abdominal disease, and if mycobacterial infection is suspected, a peritoneal biopsy specimen should be obtained for culture.

Fungal Peritonitis

If peritonitis is caused by yeasts or fungi, the peritoneal catheter should always be removed. This should be combined with anti-fungal treatment using fluconazole, with flucytosine initially intraperitoneally until sensitivities are known. Oral antifungals

should be continued for at least 10 days and up to 4 weeks after catheter removal, at which point catheter replacement can be considered.²⁵

Relapsing Peritonitis

Relapsing or recurrent peritonitis is defined as a separate infective episode caused by the same organism within 4 weeks of completion of an appropriate course of antibiotics. In the case of a relapsing gram-positive infection, a 4-week course of intraperitoneal cephalosporin together with oral rifampin should be tried. Recurrence of *S. aureus* infection should trigger the search for pericatheter infection. Relapsing MRSA peritonitis will require a prolonged course (4 weeks) of intraperitoneal vancomycin or clindamycin. If enterococci or gram-negative organisms are the cause of a relapse, the possibility of intra-abdominal disease or an abscess should be considered (although these organisms are frequently water-borne). If a patient has other gastrointestinal symptoms, such as change in bowel habit, colonoscopy should be performed, but this is essential only if multiple organisms have been isolated. Again, a repeated course of antibiotics chosen by sensitivity testing should last 4 weeks. Removal of the catheter should be considered if there is no improvement within 4 days of commencing treatment or earlier if it is clinically indicated. Current practice in most units is to allow a period of up to 3 weeks before a new catheter is inserted. Simultaneous removal and replacement of the catheter, under antibiotic cover, can be achieved successfully when the causative organism is a skin commensal.

Prevention of Peritonitis

The latest ISPD guidelines place increased emphasis on prevention of peritonitis. Antibiotic cover with vancomycin (1 g) at the time of catheter insertion is recommended to prevent subsequent exit site infection and peritonitis.²⁵ No particular catheter design has been shown to reduce infection rates, but a downward-pointing exit site of the catheter assists in catheter care. Enhanced training schedules and improved exit site care have been shown in a randomized study to reduce infection rates.²⁷ Flush-before-fill dialysate delivery systems have been shown to reduce infections associated with touch contamination and should now be standard.²⁸

S. aureus nasal carriage is associated with an increased chance of peritonitis caused by this organism. Daily use of mupirocin either intranasally or applied to the catheter exit site reduces the rate of *S. aureus* peritonitis; occasional resistance has been reported, but this has not been a significant problem to date. Of greater concern is a relative increase in infections due to *Pseudomonas*.²⁶ One randomized trial has shown a reduction in *Pseudomonas* peritonitis associated with topical gentamicin applied to the exit site (see later discussion).²⁹

Eosinophilic Peritonitis

Eosinophilic peritonitis is diagnosed when a patient presents with a cloudy bag of effluent containing eosinophils rather than neutrophils. The fluid is also culture negative. It is an uncommon event but tends to occur within the first few weeks of starting PD. The cause is unknown but assumed to be some form of reaction to the catheter or the dialysate. The condition is usually self-limited, and no treatment is required.

Exit Site Infection

Exit site infection is an important complication of long-term PD, occurring on average at a rate of 0.48 episode per patient-year. The diagnosis is suspected on clinical grounds, usually by the presence of marked erythema or discharge from the exit site (Fig. 93.11). A scoring system for exit sites has been developed to determine the likelihood of infection and to grade its severity, with 1 or 2 points awarded for crusting, swelling, pain, and discharge according to severity (score >4 indicates infection), although if the discharge is purulent, this mandates treatment.²⁵ Extension of the infection into the tunnel may be assessed either clinically or by ultrasound, enabling measurement of any abscess formation. The most common infecting organism is *S. aureus*.

Figure 93.11 Exit site infection. A severe exit site infection that has exposed the outer cuff of the catheter.

Regular use of topical mupirocin can reduce the frequency of infection episodes substantially with the additional benefit of reducing the risk of peritonitis due to this organism. Otherwise, the most common pathogen is *Pseudomonas*. A recent randomized trial comparing mupirocin and gentamicin cream at the exit site found that both staphylococcal and pseudomonal infections (exit site and peritonitis) were less common in those using gentamicin. Whereas regular application of gentamicin to exit sites infected at any stage with gram-negative organisms is currently advised, the routine application of gentamicin cream for all patients raises concerns about bacterial resistance, although this has not yet been reported.²⁹

All suspected exit site infections should be swabbed. Initial treatment should be with an antibiotic effective against *S. aureus* unless there is prior evidence that the patient carries MRSA or *Pseudomonas*, for example, flucloxacillin (500 mg four times a day) or a cephalosporin if the patient is allergic to penicillin. In most patients, the drug can be given orally; but if the individual is systemically ill, the antibiotics should be administered intravenously until clinical improvement occurs. Hospitalization, parenteral antibiotics, and often urgent catheter removal are required if there is evidence of spread into the tunnel. If the infection is MRSA, eradication therapy should be attempted with systemic vancomycin, as for peritonitis. Should the culture grow a gram-negative organism, ciprofloxacin (500 mg twice a day orally) will be effective empiric treatment in most patients.

Treatment is recommended for a minimum of 2 weeks. In gram-positive infections, if there is no improvement within 7 days, rifampin (600 mg/day) can be added. If complete healing does not take place after 4 weeks of therapy, further measures should be considered, such as exteriorizing and shaving the outer cuff. Should this cuff be visible or even close to the exit site, it is likely to be involved in the infection. There is often temporary resolution of infection after this procedure. If, despite this step, the infection persists or relapses, catheter removal must be considered because there is a high risk that the exit site infection will lead to peritonitis. It is important that the new exit site be formed in a different part of the anterior abdominal wall. If the infection is controlled and there is no evidence of sepsis along the tunnel, it is possible to insert a new catheter under antibiotic cover at the same time as the old one is removed.

Dialytic Therapies for Drug Overdose and Poisoning

Nigel S. Kanagasundaram, Andrew Lewington

Poisoning and drug overdose, whether intentional or accidental, remain common medical emergencies, accounting for more than 100,000 hospital admissions per year in the United Kingdom (around 1% of all admissions).¹ Most human exposures, however, do not require hospital admission; 73% of the nearly 2.5 million cases in the United States in 2007 were managed at the site of the incident, in a non-health care facility.² The spectrum of agents ingested is wide, ranging from overdose of prescription or proprietary drugs to poisoning with nonpharmacologic substances and recreational drugs.

The pattern of toxin ingestion has changed over the years but also varies according to geographic location. Frequently implicated agents in industrialized societies include analgesics (acetaminophen, opioids, salicylates), antidepressants, sedatives, and antipsychotics. Barbiturate poisoning is now less common but was in the past a major contributor. Pesticides remain a frequent cause of poisoning in areas of the developing world.³ Changes in legislation have been instituted to try to affect availability of potential toxins; in the United Kingdom, for instance, paraquat was withdrawn from sale in July 2008, although this has yet to be reflected in the incidence of poisoning because stored product is still available.¹

U.S. data indicate a low mortality rate, 1239 attributable fatalities in 2007 of 2.5 million episodes.² However, poisoning remains a major cause of death in young people.³

The mainstays of management include hemodynamic, respiratory, and other supportive care; prevention of further drug absorption (oral activated charcoal in specific cases); neutralization of drug toxicity (e.g., intravenous *N*-acetylcysteine after significant acetaminophen overdose or Digibind for digitoxicity); and enhancement of drug elimination.

Extracorporeal therapy is one method of achieving poison removal, either by dialysis or by a nondialytic technique, such as hemoperfusion. These enhanced elimination techniques are only occasionally needed. Just more than 2100 patients have been recorded as requiring extracorporeal therapy in the United States in 2007.² In that report, the treatment was predominantly hemodialysis, with only 16 cases recorded as receiving hemoperfusion, a decline in use of hemoperfusion perhaps due to the rarity of theophylline and barbiturate overdose in the modern era, as historically these two agents were the main indications for hemoperfusion.

Aspects of the management of poisoning beyond those related to extracorporeal therapies are well covered through resources such as TOXBASE in the United Kingdom (www.toxbase.org) and those of the American Association of Poison Control Centers (www.aapcc.org). Other local and regional poisons information

services are linked through the Web site of the European Association of Poisons Centres and Clinical Toxicologists (www.eapcct.org).

TREATMENT MODALITIES

Intermittent Hemodialysis and Hemofiltration

Diffusion against a steep concentration gradient, the physical process employed in intermittent hemodialysis, encourages the rapid removal of the smaller solutes that are the usual agents of overdose. Clearances can be enhanced by increasing dialyzer efficiency (indicated by the K_dA , the urea mass transfer area coefficient) or membrane surface area. Larger solute removal can be enhanced by increasing dialyzer flux when intermittent hemodialysis is used (for toxins >500 d and up to 10,000 d, e.g., deferoxamine, aminoglycosides) or by switching to hemofiltration (usually applied continuously; see later), in which the physical process of higher volume convection and larger membrane pore size can allow removal of toxins up to ~40,000 d.

A range of physical and biologic factors determine whether a given toxin can be eliminated by hemodialysis and whether that elimination is actually therapeutic (Fig. 94.1). In addition to molecular weight, other important physical characteristics relevant to dialyzability are water solubility and the degree of protein binding.

In each individual case, it should be determined whether hemodialysis is expected to contribute significantly to total toxin removal. Dialysis will have a limited impact if the rate of drug removal is significantly faster by endogenous routes. The risks of therapy (acute transfer to a specialist center, vascular access, anticoagulation) also have to be balanced against the clinical relevance of any gain in drug elimination. If endogenous elimination is minimal, either because these routes are naturally limited or because of toxin-associated attenuation of elimination (liver or renal failure, for instance), hemodialysis can be effective. It is generally accepted that if at least 30% can be added to total body clearance by extracorporeal treatment, its use is justified. This is not a threshold that is readily derived at the bedside without knowledge of endogenous clearance rates and the expected contribution from exogenous therapy. The summary of product characteristics may help determine the endogenous clearance rate (at least for pharmaceuticals; available from, for instance, www.emc.medicines.org.uk) but may not account for the impact of disease on specific endogenous routes of elimination. An estimate of dialyzer clearances of a variety of solutes of different molecular weights can be obtained from its product insert. For

Factors Affecting Toxin Removal by Hemodialysis	
Molecular weight	
Water solubility	
Degree of protein binding	
Significance of dialytic toxin removal relative to endogenous routes of clearance	
Theoretical volume of distribution	
Degree of solute compartmentalisation

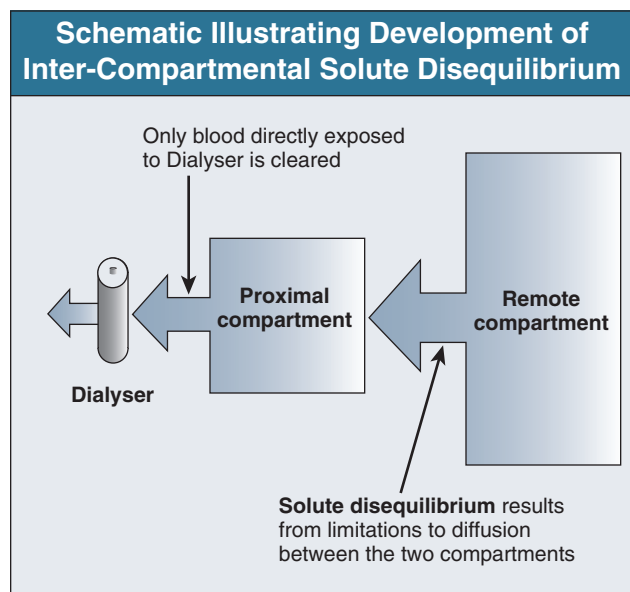

Figure 94.2 Intercompartmental solute disequilibrium. Access of dialyzer to toxin is limited by disequilibrium, which retains toxin in remote compartment.

hemofiltration (see later, Continuous Renal Replacement Therapy), an estimate of clearance can be provided by the ultrafiltration rate.

The efficacy of toxin removal is also influenced by its theoretical volume of distribution (V_D). Substances confined to the blood stream will have a low V_D (~ 0.07 l/kg body weight); those distributed in the extracellular space, a V_D of ~ 0.2 l/kg; and those confined to total body water, ~ 0.6 l/kg. Higher distribution volumes are, however, not uncommonly found in those substances with avid tissue binding or sequestration. As V_D increases, more solute must be removed to achieve a particular blood level. The ideal solute would therefore have a low distribution volume, which would also be a single, well-mixed compartment that is directly accessible by the dialysis process. However, as shown in Figure 94.2, solute is often distributed across at least one remote body compartment that is not directly accessible during hemodialysis. If there is any resistance to solute movement between the accessible proximal and remote compartments, disequilibrium will develop during the course of the dialysis session, reducing the overall efficiency of toxin removal. This may be significant, as in the case of lithium, and will be manifested as a large, post-

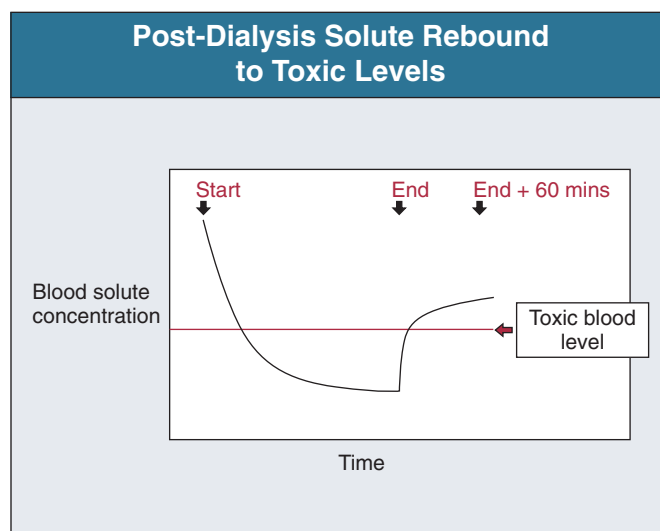

Figure 94.3 Post-dialysis solute rebound. Falling solute concentration during dialysis with rapid postdialysis rebound to toxic levels.

dialysis rebound in blood levels as solute re-equilibrates from the remote compartment. A significant solute rebound to a potentially toxic level may be missed if the immediate postdialysis blood level is relied on as a measure of elimination (Fig. 94.3).

Extending the hemodialysis session beyond 4 hours can to some extent ameliorate rebound, but intermittent hemodialysis is an inherently inefficient process that depends on the solute concentration presented to the dialyzer. Most solute removal occurs at the start of dialysis. Any gains in solute removal will be disproportionately low in comparison to the increases in dialysis time. An alternative or adjunctive solution is to increase dialysis session frequency.

Compartmentalization need not preclude hemodialysis-related toxin removal, but the closer that its distribution is to a single compartment, the easier that removal becomes.

In summary, intermittent hemodialysis is usually the first-choice extracorporeal modality because of its common availability, the rapidity of toxin removal, and the low molecular weight of the common agents of poisoning. The role of other renal replacement modalities is less clear because of a lack of published data.

Peritoneal Dialysis

Peritoneal dialysis is rarely used in the treatment of poisoning because of the comparatively slow rate of clearance, the risks associated with acute peritoneal dialysis catheter insertion, and the widespread availability of extracorporeal techniques (at least in the industrialized world). It may have a role in the treatment of poisoning in children as the lower clearance may be sufficient for their smaller solute distribution volumes. There may, in addition, be technical challenges making hemodialysis less satisfactory, especially in very young children.

Continuous Renal Replacement Therapy

Continuous renal replacement therapy (CRRT) may be used when intermittent hemodialysis is not immediately available or when more rapid solute removal will be compromised by significant intercompartmental disequilibrium. For small solute

clearances, continuous hemofiltration and continuous hemodialysis have nearly kinetic equivalence; full saturation of dialysate effluent in continuous hemodialysis, due to its slow flow rates, gives it a small solute concentration similar to both the ultrafiltrate from hemofiltration and plasma water as it leaves the hollow-fiber device. CRRT gives better longer term solute clearances (during the course of several days) but does not provide the rapidity of elimination afforded by intermittent hemodialysis when minimizing toxin exposure is a high priority. Delivered small solute clearances of CRRT can be maximized by combining techniques in the form of continuous hemodiafiltration. If it is logistically possible, an ideal combination may be initial use of intermittent hemodialysis for rapid reduction of toxin levels, with continuous therapy then being applied to ameliorate any postdialysis rebound, where this is predicted. Although combining some of the advantages of both continuous and intermittent techniques, the role for hybrid modalities, such as sustained low-efficiency dialysis (SLED), requires further evaluation.

Although small solute clearances are similar in continuous hemofiltration and continuous hemodialysis, continuous hemofiltration should be used in preference if larger toxins (as described earlier for intermittent hemodialysis) require removal.

Renal replacement therapy is also indicated for acute kidney injury (AKI), which can result from ingestion of a variety of different agents (e.g., acetaminophen), and for other complications of poisoning, such as pulmonary edema, electrolyte and acid-base disturbances, and hypothermia and hyperthermia.

Because renal replacement therapy modalities are often applied for drug elimination in the absence of any actual renal dysfunction or serious electrolyte disturbance, careful monitoring for evolving biochemical abnormalities is required. Hypokalemia can be corrected by adjusting the dialysate or replacement fluid composition and by supplementation. Hypophosphatemia can be addressed with standard supplements. At least for intermittent hemodialysis, the risk for development of a metabolic alkalosis can be attenuated by dialing in a dialysate bicarbonate concentration at the lower end of the physiologic range, provided there is no coexistent renal impairment and no metabolic acidosis or the risk of it. Manipulation of the bicarbonate concentration of premanufactured replacement or dialysate fluid in CRRT is not practical; this is another advantage of intermittent hemodialysis in this setting because it affords flexibility of bicarbonate dialysate concentration if a severe metabolic alkalosis is present.

Hemoperfusion

The technique involves the extracorporeal circulation of blood through a hemoperfusion cartridge (Fig. 94.4) containing an adsorbent material such as activated charcoal or a resin. The charcoal sorbent particles are coated with a polymer to increase biocompatibility and to reduce the risk of thrombocytopenia. Hemoperfusion removes those substances that can bind to the adsorbent material. It is effective at removal of uncharged molecules through competitive binding, especially those that are significantly plasma protein bound and lipophilic. As with hemodialysis and hemofiltration, the likely proportional contribution to total toxin elimination should be considered before embarking on hemoperfusion.

Other than the cartridge itself and the lack of dialysate and other replacement fluid circuits, the disposables and hardware are those used for standard intermittent hemodialysis (Fig. 94.5). It is much less widely available than hemodialysis or

Figure 94.4 A charcoal hemoperfusion cartridge.

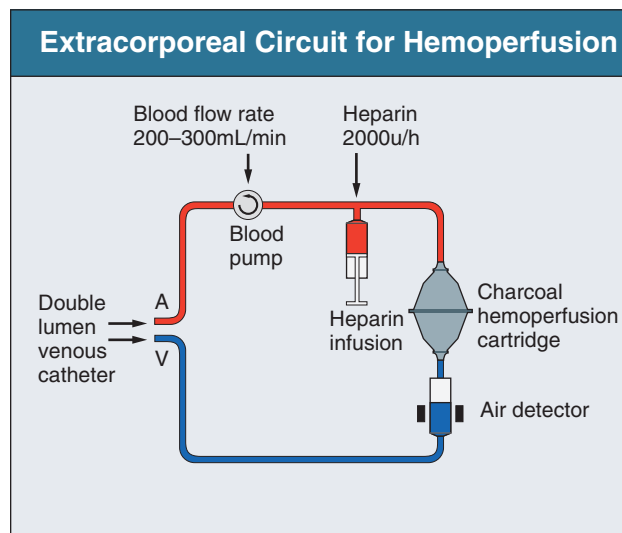

Figure 94.5 Extracorporeal circuit for hemoperfusion.

hemofiltration but may have its principal utility in the removal of protein-bound drugs that are not eliminated effectively by those modalities.⁴

Standard anticoagulation protocols may be insufficient for hemoperfusion as heparin is also adsorbed. A larger unfractionated heparin initial bolus and maintenance dose (e.g., ≥ 2000 U/h) is usually required, with subsequent adjustments guided by regular monitoring of clotting times during the procedure. The cartridge manufacturer's instructions should be reviewed carefully, as some require specific priming with dextrose solution to prevent hypoglycemia. Other complications include hypocalcemia, charcoal embolization, leukopenia, thrombocytopenia, and adsorption of coagulation factors.

Saturation of the adsorbent material limits the duration of treatment with any individual hemoperfusion cartridge to around 3 hours, although this is usually adequate for a significant lowering of blood levels. Continuous hemoperfusion can help attenuate the post-session rebound that can occur with intermittent treatment, with cartridges being changed every 4 hours.

If a toxin is equally removed by intermittent hemodialysis and hemoperfusion, intermittent hemodialysis should be used preferentially as it also allows fluid, electrolyte, and other metabolic control. Combined hemoperfusion-hemodialysis has also been used but only rarely, and its role is not defined.

Some Poisonings for which Extracorporeal Removal May be Indicated		
Hemodialysis	Hemofiltration	Hemoperfusion
Alcohols Ethanol Methanol Ethylene glycol Isopropanol	Aminoglycosides Desferoxamine Sodium edetate Theophylline	<i>Amanita</i> mushroom Barbiturates Carbamazepine Meprobamate Theophylline
Betablockers Atenolol Sotalol		
Lithium		
Meprobamate		
Metformin		
Salicylates		
Theophylline		

Figure 94.6 Some poisonings for which extracorporeal removal may be indicated.

Other Modalities

There are a few reports of the use of plasma exchange and the molecular adsorbent recirculating system (MARS) in poisoning. In principle, both should be useful for those toxins that are strongly protein bound. Plasma exchange can also clear the red cell fragments and free hemoglobin that result from poisoning with sodium chlorate or other agents that can cause hemolysis.

WHEN SHOULD EXTRACORPOREAL REMOVAL BE CONSIDERED?

A wide range of drugs and other toxins can be removed by extracorporeal therapy, but those for which such treatment may actually be indicated is much more limited as supportive measures and orally administered activated charcoal may be equally effective. More common indications for extracorporeal drug removal are shown in [Figure 94.6](#).

Principles guiding the decision to deploy extracorporeal therapy are shown in [Figure 94.7](#).

EXTRACORPOREAL THERAPY FOR SPECIFIC DRUGS AND POISONS

Alcohols

Ethylene glycol and methanol poisoning may present with nausea, vomiting, abdominal pain, impaired consciousness that may progress to severe metabolic acidosis, AKI, optic nerve damage, convulsions, coma, and ultimately death. The presence of needle-shaped crystals of calcium oxalate monohydrate in the urine is pathognomonic for ethylene glycol toxicity. Ingestion of relatively small amounts of ethylene glycol and methanol may result in significant toxicity (see Chapter 12). This toxicity results from metabolism of ethylene glycol and methanol by alcohol dehydrogenase to the toxic metabolites formic acid and glycolic acid, respectively.

Early recognition is essential, allowing institution of treatment to inhibit alcohol dehydrogenase with ethanol or fomepizole. Fomepizole has now replaced ethanol as first-line therapy^{5,6};

Criteria for Considering Extracorporeal Therapy for a Removable Substance

Toxic blood levels (if a threshold of toxicity can be defined)
Serious clinical manifestations despite optimal support
Delayed action possible (e.g. ethylene glycol, methanol, paraquat)
Metabolic effects (e.g. acidosis)
Endogenous routes of clearance, impaired (e.g. liver or renal failure)

Figure 94.7 Criteria for considering extracorporeal therapy for poisoning.

it is safe with minimal side effects, and although it is expensive, this can be offset compared with the increased cost of hemodialysis and intensive care unit admission if fomepizole is not used.

Fomepizole should be prescribed if there is a clear history of ethylene glycol or methanol ingestion with an osmolal gap above 10 (indicating significant toxicity) or the ethylene glycol or methanol blood level is more than 200 mg/l. Fomepizole is administered as a loading dose of 15 mg/kg intravenously. This is then followed by 10 mg/kg every 12 hours for four doses and then 15 mg/kg every 12 hours until the metabolic acidosis has resolved and the serum concentration of ethylene glycol and methanol is less than 200 mg/l or less than 100 mg/l in the presence of end-organ damage. Patients who have ingested methanol should also receive folinic acid, 50 mg intravenously every 6 hours, to enhance the metabolism of formic acid. If fomepizole is not available, intravenous 10% ethanol should be administered as a loading dose of 10 ml/kg followed by an infusion of 0.15 ml/kg per hour to achieve a serum ethanol concentration of about 1 to 1.5 g/l. Ethanol should be administered until no ethylene glycol or methanol is detectable in the blood.

Immediate hemodialysis is recommended if ingestion of ethylene glycol or methanol is confirmed with serum concentration of more than 500 mg/l in the setting of severe metabolic acidosis or the presence of end-organ damage such as AKI or visual disturbance. It is important to recognize that fomepizole is removed by hemodialysis. Therefore, if a loading dose of fomepizole has already been administered, a continuous infusion of 1 to 1.5 mg/kg per hour should be prescribed for the duration of the hemodialysis. Similarly, if ethanol has been used as a competitive inhibitor of alcohol dehydrogenase, its dose will have to be doubled because of its removal by hemodialysis.

To achieve optimal clearance, the dialyzer should have a large surface area ($>1.5 \text{ m}^2$) and the blood flow rate should be more than 300 ml/min. Bicarbonate buffer should be used, and serum concentrations of ethylene glycol and methanol should be measured 2 hours after cessation of treatment to take account of rebound. Patients who have ingested large quantities of ethylene glycol and methanol may require further hemodialysis. Continuous extracorporeal treatment is less effective in removal of ethylene glycol and methanol but may be used if intermittent hemodialysis is not available.

β-Blockers

Symptomatic β-blocker overdose will be manifested within 4 hours of ingestion in the majority of patients with bradycardia and hypotension. Clinical presentation may also include changes in mental status, seizures, bronchospasm, and hypoglycemia. An

increased risk of severe toxicity occurs in patients who have co-ingested other drugs that act on the cardiovascular system. The principles of medical management involve implementation of immediate life support. Bradycardia can be treated with intravenous atropine at 0.5 to 1 mg, and bronchospasm can be treated initially with high-dose nebulized salbutamol. Intravenous fluids (crystalloid) should be administered to treat hypotension. Symptomatic hypoglycemia requires intravenous dextrose. Activated charcoal should be administered orally to all patients presenting within 1 to 2 hours of β -blocker overdose.

Extracorporeal removal of β -blockers is rarely required and only in those patients who have not improved despite maximal medical therapy. Extracorporeal removal is effective only for hydrophilic, minimally protein bound drugs such as atenolol, sotalol, nadolol, and acebutolol. Intermittent hemodialysis is recommended in hemodynamically stable patients. Continuous venovenous hemodialysis or continuous venovenous hemodiafiltration may be considered in patients who are hemodynamically unstable. There are few data regarding the effectiveness of β -blocker removal by continuous venovenous hemofiltration.

Lithium

In cases of severe lithium poisoning, patients may present with arrhythmias, hypotension, confusion, coma, or seizures. Hemodialysis is recommended if the serum lithium concentration is above 4 mmol/l or above 2.5 mmol/l in a patient with central nervous system manifestations. Lithium (M_r 74 d) is removed easily by hemodialysis because of its low molecular weight and negligible protein binding. The clearance of lithium by hemodialysis is superior to that achieved by the kidneys, which is limited by significant proximal tubule reabsorption of lithium. Because lithium equilibrates relatively slowly between the extracellular and intracellular compartments, a rebound increase in serum levels of lithium follows hemodialysis.⁷ Therefore, extended⁸ or frequent hemodialysis treatment may be needed to minimize the impact of disequilibrium. Serum lithium levels should be checked 6 hours after completion of treatment to guide further therapy. Continuous modalities, including continuous venovenous hemodialysis and continuous venovenous hemofiltration, may be advantageous and have been used successfully.⁹

Metformin

Metformin (M_r 166 d) overdose can present with a severe lactic acidosis. Medical management will involve immediate life support and the intravenous administration of sodium bicarbonate. In patients who are unresponsive to medical management or who also present with AKI, extracorporeal therapy will be necessary to correct the acidosis. Intermittent hemodialysis is effective, and more recently there have been reports of successful continuous extracorporeal therapy, including continuous venovenous hemofiltration.¹⁰

Salicylates

The clinical manifestations of salicylate overdose include fever, sweating, tinnitus, epigastric pain, nausea, vomiting, diarrhea, vertigo, and blurring of vision. In severe overdoses, clinical presentation may progress to depression of mental status, noncardiogenic pulmonary edema, and death. Salicylate intoxication initially results in activation of the respiratory center with hyperventilation and a respiratory alkalosis. This is then followed by

a metabolic acidosis due to the accumulation of lactic acid and keto acids. Therefore, the patient may present with either a respiratory alkalosis or a mixed respiratory alkalosis–metabolic acidosis. Diagnosis is based on the presenting history and clinical examination and confirmed with plasma salicylate levels. Moderate toxicity occurs with salicylate levels above 500 mg/l. Ingestion of enteric-coated salicylate preparations may delay detection of peak levels for up to 36 hours.

General management includes immediate life support and stabilization of the patient. Gastric lavage should be attempted up to 12 hours after ingestion if the airway is protected, and activated charcoal should be administered orally. Hypoglycemia should be treated with intravenous dextrose.

Increased salicylate tissue penetration and toxicity can occur with only small decreases in the pH because of increased concentration of nonionized salicylate. Intravenous sodium bicarbonate should be given to decrease tissue penetration and to facilitate the excretion of salicylate through the kidneys. Sodium bicarbonate can be administered as an initial bolus of 1 to 2 mmol/kg of 8.4% sodium bicarbonate and then as an infusion of 150 mmol of sodium bicarbonate in 1 liter of 5% dextrose during 2 hours. Blood pH should be measured every 2 hours and the pH kept between 7.5 and 7.55 (not rising above a pH of 7.6). Urinary volume should be monitored, and urinary pH should be kept above 7.5 to optimize salicylate excretion. Urinary alkalization is contraindicated if the patient has AKI, pulmonary edema, or cerebral edema.

Extracorporeal therapy is indicated in patients who do not respond to this medical management. It is also indicated in patients who have AKI (preventing salicylate excretion), pulmonary edema, or altered mental status or in whom the serum salicylate concentration is more than 800 mg/l. Intermittent hemodialysis has the advantage over hemoperfusion because of its more rapid correction of associated electrolyte abnormalities and acidemia. There are few data on use of continuous venovenous hemofiltration.

Theophylline

The clinical presentation of theophylline overdose includes nausea, vomiting, diarrhea, gastrointestinal hemorrhage, hypokalemia, seizures, arrhythmias, and hypotension. Indications for extracorporeal removal of theophylline include acute intoxication with a serum level above 100 mg/l, chronic intoxication in a patient older than 60 years with a serum level above 40 mg/l, and recurrent seizure activity. Theophylline is readily cleared by either hemodialysis or hemoperfusion because of its low volume of distribution.¹¹ Hemoperfusion is preferred to hemodialysis because of higher removal rates unless there are severe electrolyte abnormalities, when hemodialysis is the preferred modality. Continuous venovenous hemofiltration can be used but requires a more sustained period of treatment.

Valproate

Valproate (M_r 144 d) overdose may present with clinical features that include mild confusion, lethargy, nausea, vomiting, tachycardia, hypotension, metabolic acidosis, and electrolyte disturbances (hyponatremia and hypocalcemia). Extracorporeal therapy is rarely indicated for the removal of valproate except in cases of refractory metabolic acidosis or hemodynamic instability. Valproate is poorly cleared despite a low molecular weight and a low volume of distribution because of its high degree of protein

binding. However, at higher serum levels (>1000 mg/l), the valproate protein-binding sites become saturated, resulting in unbound free drug. Hemodialysis and hemoperfusion readily clear the unbound drug and reverse associated metabolic abnormalities.¹² Despite a number of case reports detailing the use of extracorporeal removal of valproate, there is no clear-cut evidence that it improves clinical outcomes.

Plasma Exchange

Jeremy Levy, Charles D. Pusey

The place of plasma exchange (plasmapheresis) in the management of renal disease has become clearer in the past 5 years, with increasing numbers of controlled studies comparing therapeutic plasma exchange with other treatments. Despite this, in many renal diseases, the quality of published data still remains poor and the precise role for plasma exchange unclear. Plasma exchange came into widespread clinical use after early reports of beneficial effects in Goodpasture's disease in the mid-1970s. It is used to remove many large-molecular-weight substances from plasma, including pathogenic antibodies, cryoglobulins, and lipoproteins. Newer techniques have also been developed to allow more selective removal of plasma components, such as double filtration plasmapheresis, cryofiltration, and immunoadsorption.

TECHNIQUES

Plasma exchange can be carried out either by centrifugal cell separators or, more commonly in renal units, with hollow-fiber plasma filters and standard hemodialysis equipment (Figs. 95.1 and 95.2). Centrifugal devices allow withdrawal of plasma from a bowl with either synchronous or intermittent return of blood cells to the patient. There is no upper limit to the molecular weight of proteins removed by this method. The bowls and circuits are single use and disposable, and blood flow rates are generally relatively low (90 to 150 ml/min). Platelet loss is a particular problem with centrifugal devices, and platelet counts can decrease by as much as 50%. Membrane plasma filtration uses highly permeable hollow fibers with membrane pores of 0.2 to 0.5 μm . Plasma readily passes through the membrane while the cells are simultaneously returned to the patient. All immunoglobulins will cross the membrane (IgG more efficiently than IgM); however, some large immune complexes and cryoglobulins may not be adequately cleared, although many membranes allow clearance of molecules up to 3 million daltons. There is no loss of platelets, but hemolysis can occur if transmembrane pressures are too high (a rare complication). Blood flow rates required are 90 to 200 ml/min; there is no increase in rate of plasma filtration at higher blood flows, but there is an increased risk of hemolysis. Membranes used in plasma filters are polysulfone, polypropylene, cellulose diacetate, polymethylmethacrylate, or polyacrylonitrile. It has been suggested that the adsorptive properties of the membrane for cytokines and other biomolecules may account for some of the beneficial effects of plasma filtration. There have been occasional reports of mild adverse reactions in patients taking angiotensin-converting enzyme inhibitors when plasma is filtered with ethylene vinyl alcohol or acrylic copolymer membranes. Reuse of plasma filters is not advised, but performance

data do not indicate a major loss of function during routine plasma exchange.

Vascular access is usually achieved with use of standard central venous catheters; but if a patient already has an arteriovenous (AV) fistula, then of course this can be used. However, it is also sometimes possible to perform plasma exchange by peripheral access through large-bore, short, intravenous cannulae, placed in the antecubital fossa, because the blood flow rates required are low. Single-needle access with an AV fistula is also relatively easy to accommodate, especially for centrifugal plasma exchange, in which the blood removal and return can be asynchronous, but also for membrane filtration. Anticoagulation is almost always needed and must be carefully managed in patients with a bleeding risk, for example, those with hemolytic-uremic syndrome, recent or ongoing pulmonary hemorrhage, or recent renal biopsy. In general, citrate is used for centrifugal plasma exchange and heparin for membrane plasma filtration; however, citrate has particular advantages in patients at higher bleeding risk in view of its lack of systemic anticoagulant actions. When heparin is used, higher doses may be needed than in hemodialysis as a result of increased losses during the procedure (heparin is protein bound). Bolus doses of unfractionated heparin 2000 to 5000 U are given initially, and then 500 to 2000 U/h. Anticoagulant is administered prefilter.

Both methods of plasma exchange require large volumes of colloid replacement. A single plasma volume exchange will lower plasma macromolecule levels by approximately 60%, and five exchanges during 5 to 10 days will clear 90% of the total body immunoglobulin (Fig. 95.3).¹ For most patients, this is achieved by removal of 50 ml of plasma per kilogram of body weight at each procedure (~4 liters for a 75-kg person). Daily plasma exchange is likely to be most effective in rapidly depleting total body load in view of redistribution of immunoglobulins from the extravascular compartments, but there is no good evidence that intensity of exchanges has a major effect on outcomes except in patients with hemolytic-uremic syndrome with poor prognostic markers (see later discussion). Indeed, alternate-day exchanges are of proven efficacy in antineutrophil cytoplasmic antibody (ANCA)-associated diseases. Replacement with crystalloid is untenable because of the need to maintain colloid oncotic pressure. Synthetic gelatin-based plasma expanders can be used as part of a replacement regimen but have a shorter half-life than human albumin, which is the mainstay replacement fluid. The major disadvantage of albumin solutions is the lack of clotting factors, with the potential development of depletion coagulopathy after plasma exchange. Fresh frozen plasma (FFP) should be given, usually in addition to human albumin solution, in patients at particular risk of bleeding. However, almost all the serious

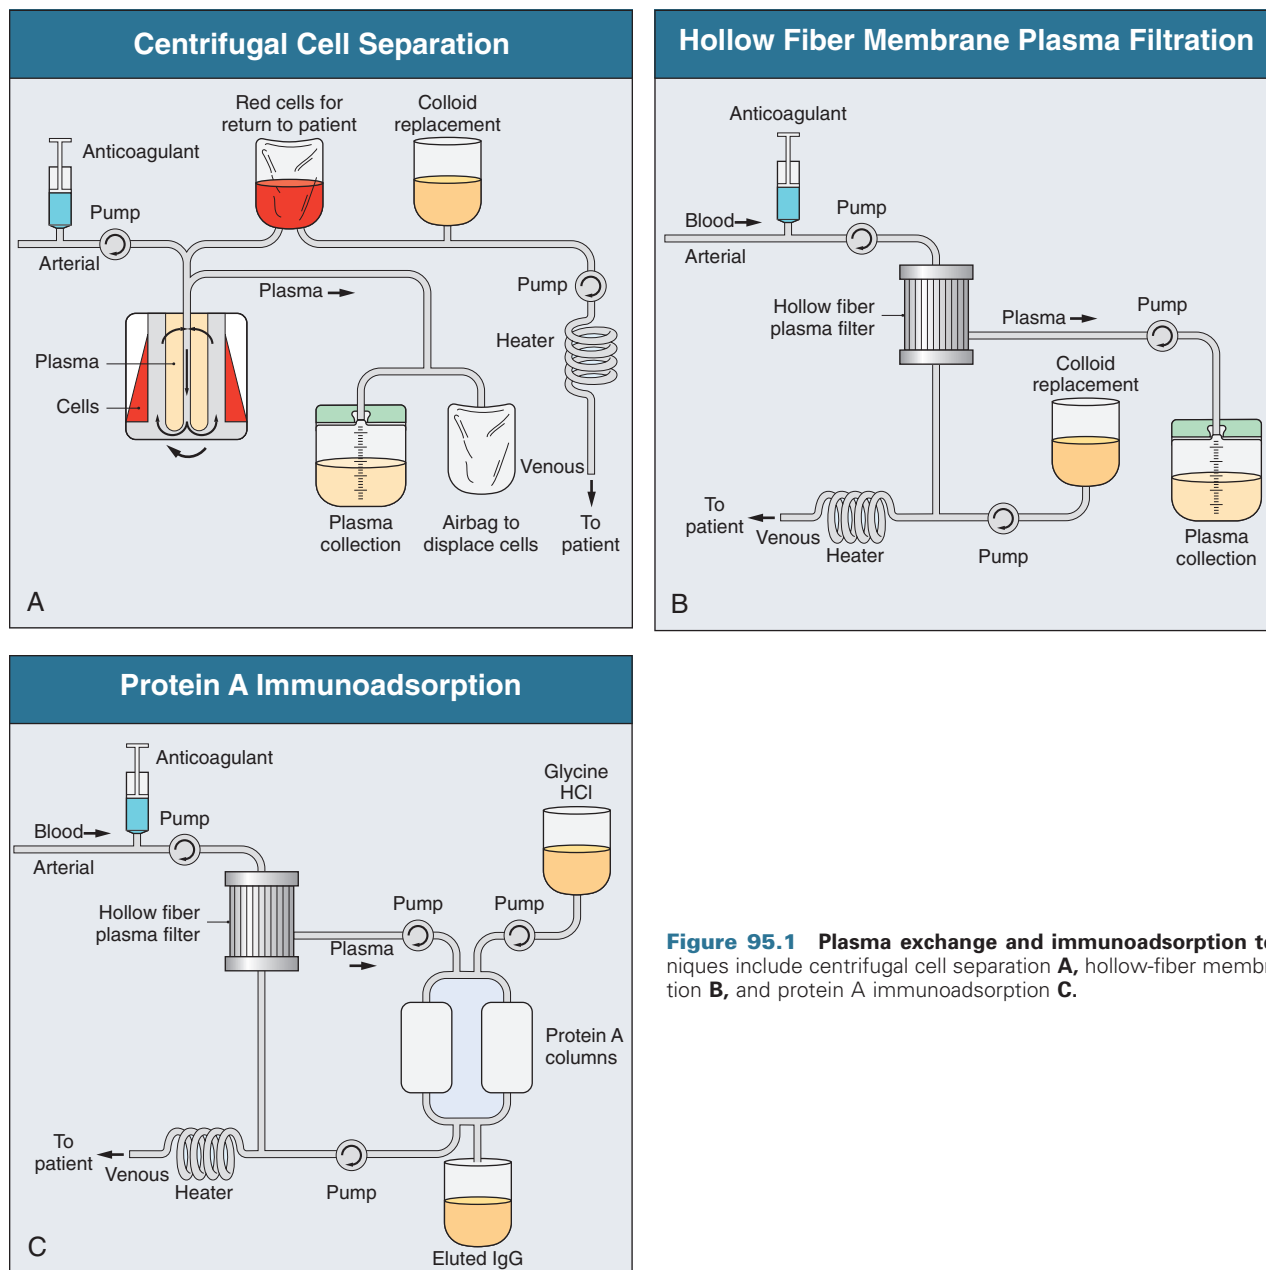

Figure 95.1 Plasma exchange and immunoadsorption techniques. Techniques include centrifugal cell separation **A**, hollow-fiber membrane plasma filtration **B**, and protein A immunoadsorption **C**.

complications of plasma exchange (hypotension, anaphylaxis, citrate-induced paresthesia, urticaria) have been reported in patients receiving FFP rather than albumin (see later discussion).^{2,3} Both human products carry a tiny risk of transmission of infectious diseases, especially viral. Standard regimens for plasma exchange are summarized in Figure 95.4. Human albumin solution should be used for all exchanges except in thrombotic microangiopathies (in which plasma should provide the total exchange; see Chapter 28), and FFP should form part of the exchange when bleeding risk is high (ongoing pulmonary hemorrhage or within 48 hours of biopsy or surgery). If fibrinogen levels decrease to less than 1.25 to 1.5 g/l or prothrombin time is increased 2 to 3 seconds above normal, FFP should also be administered.

Double filtration plasmapheresis (or cascade filtration) uses membrane filtration to separate cells from plasma and then a

secondary plasma filtration (pore size, 0.01 to 0.03 μm) to remove plasma solutes based on molecular size. Most albumin is therefore returned to the patient together with lower molecular weight proteins, reducing the need for replacement fluids. Cryofiltration uses a similar principle but exposes the filtrate to 4°C during the procedure, with the aim of precipitating cryoproteins. These techniques are not widely available.

Selective and specific immunoadsorption techniques are increasingly available. Protein A immunoadsorption has been used to remove immunoglobulin alone from plasma, without the need for replacement fluids and without depletion of clotting factors and complement (see Fig. 95.1C). Protein A selectively binds the Fc domains of immunoglobulin molecules, and the immunoadsorption columns can be repeatedly regenerated. Columns have been used for 1 year for a single patient on up to 30 occasions; however, the repeated acid stripping during

Regimens for Plasma Exchange in Renal Disease					
Indication	Antiglomerular Basement Membrane Antibody (anti-GBM) Disease	Small Vessel Vasculitis	Cryoglobulinemia	Recurrent FSGS After Transplantation	HUS/TTP
Duration of treatment	Daily, at least 14 days until anti-GBM antibodies 20%	Daily, 7–10 days depending on clinical response	At least 7–10 days or until clinical response	Daily, at least 10 days initially, then continuing less frequently, often for months	Daily for 7–10 days or until platelet count $80\text{--}100 \times 10^9/\text{l}$ (sometimes needed twice daily)
Exchange volume	50 ml/kg each treatment	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease
Replacement fluid	Human albumin 5% (unless bleeding risk)	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease	Fresh-frozen plasma (FFP) or cryo-poor FFP
Additions to replacement fluid	20 ml 10% calcium gluconate (occasionally more), 3 ml 15% KCl if not dialysis dependent, heparin 5000–10,000 U (unless citrate anticoagulation)	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease	As for anti-GBM disease (may need more calcium because of increased volume of FFP-containing citrate)
Immunosuppression	Prednisolone and cyclophosphamide	As for anti-GBM disease	Prednisolone and cyclophosphamide in type II (caution if HCV positive)	None	None
Variations	FFP 5–8 ml/kg as part of exchange volume if hemorrhage risk (renal biopsy in last 48 hr, lung hemorrhage, platelets $<40 \times 10^9/\text{l}$, fibrinogen $<1.5 \text{ g/l}$); immunoadsorption may be as effective	As for anti-GBM disease Immunoadsorption may be as effective	As for anti-GBM disease	As for anti-GBM disease; may need to include replacement immunoglobulins if continuing long term; immunoadsorption may be as effective

regeneration does reduce the efficacy of antibody binding. This technique has been used to treat conditions in which autoantibodies are thought to play a key pathogenic role and usually in place of plasma exchange, such as in Goodpasture's disease, rheumatoid arthritis, and systemic lupus vasculitis, and to remove anti-ABO or anti-HLA antibodies in highly sensitized transplant recipients. In general, the reported efficacy has been equal to that of plasma exchange. Specific ligands have also been immobilized onto columns for more specific removal of potentially pathogenic serum factors; ligands used include anti-human IgG, C1q, phenylalanine, hydrophobic amino acids, acetylcholine receptor and β -adrenoreceptor peptides, and blood group-related oligosaccharides.

COMPLICATIONS

Plasma exchange is expensive (mostly the cost of replacement fluids) and time-consuming and requires trained staff and large-bore vascular access. However, the complication rate is not high. The Swedish registry reported no fatalities during 20,485 procedures and an overall adverse incidence rate of only 4.3% of all exchanges (0.9% for severe adverse events), of which 27% were paresthesias, 19% transient hypotension, 13% urticaria, and 8% nausea.³ The Canadian apheresis registry has collected data on 144,432 apheresis procedures since 1981 and reported adverse events occurring in 12% of procedures (mostly minor) and overall in 40% of patients. Severe events occurred in only 0.4% of procedures. Three deaths were probably related directly to the procedure, one from a transfusion-related acute lung injury and two from complications from central venous catheters.⁴ An overall complication rate of 1.4% has been reported in more than 15,000 treatments in patients receiving albumin and 20% in patients receiving FFP.^{2,3} Plasma exchange by centrifugation had a lower risk for adverse events than by filtration.

Other complications directly attributable to plasma exchange include citrate-induced hypocalcemia (presenting with perioral tingling and paresthesias) and citrate-induced metabolic alkalosis. Citrate is usually present in FFP (up to 14% by volume) or is administered in the extracorporeal circuit as an anticoagulant; it binds free calcium in plasma. Symptomatic hypocalcemia can be averted by infusion of 10 to 20 ml of 10% calcium gluconate during each plasma exchange. Alkalosis is rare and is caused by metabolism of citrate to bicarbonate and failure to excrete bicarbonate in patients with renal impairment.

Plasma exchange predictably increases the risk of bleeding as a result of depletion of coagulation factors in patients receiving albumin as sole replacement colloid. Prothrombin time is increased by 30% and partial thromboplastin time by 100% after a single plasma volume exchange. Patients at risk of bleeding (pulmonary hemorrhage, after biopsy, postoperative) should receive FFP (300 to 600 ml) with replacement fluids. Dilutional hypokalemia is avoided by adding potassium to the replacement albumin. An increased incidence of infection secondary to hypogammaglobulinemia has not been confirmed in recent series.⁴ Sepsis related to intravenous access is the most common infectious complication of plasma exchange. Cascade filtration can lead to hemolysis (in up to 20% patients) but rarely necessitates transfusion.

MECHANISMS OF ACTION

Plasma exchange removes large-molecular-weight substances from the plasma, including antibodies, complement components,

immune complexes, endotoxin, lipoproteins, and von Willebrand factor (vWF) multimers. The pathogenicity of autoantibodies in anti-glomerular basement membrane (anti-GBM) disease provided the impetus for development of plasma exchange therapy, but it is now clear that antibodies, although necessary, are not alone sufficient to cause the necrotizing glomerulonephritis in Goodpasture's disease. Therefore, plasma exchange may well have benefits in addition to simply clearance of autoantibodies. The clearance of antibodies from patients is variable and depends on a number of factors, including the rate of equilibration of macromolecules between the intravascular and extravascular compartments. IgM antibodies are cleared more effectively by centrifugal plasma exchange than are other classes of immunoglobulin as they are retained in the vascular compartment almost wholly. Rebound increase in antibody production will occur unless there is concomitant immunosuppression to prevent resynthesis.

Plasma exchange has also been shown to remove immune complexes, which may have clinical significance in cryoglobulinemia and systemic lupus, and fibrinogen and complement components. There is no good evidence that removal of cytokines has any clinical significance. Plasma exchange reduces plasma viscosity, with consequent improved blood flow in the microvasculature.

INDICATIONS FOR PLASMA EXCHANGE

Evidence to support specific indications for plasma exchange is variable in quality. Direct comparison between randomized controlled trials can be unsatisfactory because of variations in dose and frequency of plasma exchange and in immunosuppressive and other adjunctive therapy. The American Society for Apheresis reviewed all indications for plasma exchange in 2007 and summarized available trial data.^{7,8} In this chapter, evidence from available randomized trials is discussed alongside observational data. The indications are summarized in [Figures 95.5 and 95.6](#).

Anti-Glomerular Basement Membrane Antibody Disease (Goodpasture's Disease)

Plasma exchange removes anti-GBM antibodies effectively. Most patients can be depleted of pathogenic antibodies after 7 to 10 plasma volume exchanges if further antibody synthesis is inhibited by the concurrent use of cyclophosphamide and corticosteroids. Before the introduction of this therapy, the mortality from Goodpasture's disease was more than 90%, and only 11% of patients who were not dialysis dependent at presentation survived with preserved renal function. The use of plasma exchange improved the outcome considerably; 70% to 90% of patients now survive. However, only 50% of survivors and no more than 10% of those who are dialysis dependent at presentation retain independent renal function. There has been only one small controlled trial of plasma exchange in the treatment of Goodpasture's disease that used a low intensity of plasma exchange.^{7,9} A total of 17 patients were randomized to receive corticosteroids and cyclophosphamide, with or without plasma exchange. Only two of the eight receiving plasma exchange developed end-stage renal disease compared with six of the nine receiving drugs alone.

Long-term data from 71 patients with Goodpasture's disease confirmed the benefit of a treatment regimen including plasma exchange because most patients with mild to moderate renal failure retained independent renal function during 10 to 25

Conditions for Which There is Strong Evidence for the Benefit of Plasma Exchange					
Indication	Randomized Controlled Trial (no. of Patients)	Controlled Trial (no. of Patients)	Case Series (no. of Patients)	Replacement Fluid	Comments
ANCA-associated systemic vasculitis	8 (300)	1 (26)	21 (294)	Albumin unless pulmonary hemorrhage or need to prevent coagulopathy	Only proven benefit in dialysis-dependent patients Should consider daily exchanges in fulminant cases or with pulmonary hemorrhage
Anti-GBM antibody disease	1 (17)	0	17 (430)	Albumin unless pulmonary hemorrhage or need to prevent coagulopathy	Minimum course 14 days to remove antibodies effectively Especially beneficial in nonoliguric patients before dialysis Patients with creatinine >5.5 mg/dl (500 μ mol/l) unlikely to benefit
Cryoglobulinemia	0	0	18 (195)	Albumin	Long-term maintenance treatment needed in some patients Ensure blood warmer on return lines or warm replacement fluids
Thrombotic thrombocytopenic purpura	3 (237)	2 (133)	17 (915)	Plasma or cryo-poor plasma	Daily; often with corticosteroids The only treatment that has improved mortality
ABO incompatible kidney transplantation	0	0	22 (>500)	Albumin +/- plasma (compatible with donor and recipient or AB)	Used before transplantation to reduce titers of antibodies and often continued for a few days after surgery Allows successful transplantation
HLA desensitization for transplantation (in highly sensitized patients)	0	1 (61)	18 (219)	Albumin	Always in combination with immunosuppression and continued until crossmatch negative Usually needs 5 plasma exchanges to reduce Ab levels sufficiently
Antibody-mediated kidney transplant rejection	3 (61)	5 (240)	24 (396)	Albumin	Daily or alternate day Significantly better evidence has emerged in the last 15 years for benefit

Figure 95.5 Conditions for which there is strong evidence for the benefit of plasma exchange. ANCA, antineutrophil cytoplasmic antibody.

years,¹⁰ and renal recovery was possible even in some of those with the most severe renal disease. Combining all the available published data for patients with Goodpasture's disease, 76% of patients presenting with serum creatinine concentration below 5.5 to 6.8 mg/dl (500 to 600 μ mol/l) will retain renal function, in contrast to 8% of those presenting dependent on dialysis.

Recommendation

All patients presenting before dialysis should receive intensive plasma exchange with daily 4-liter exchanges initially for 14 days (regimen shown in Fig. 95.5). For dialysis-dependent patients, we recommend plasma exchange with immunosuppression only for those who have biopsy or clinical evidence of recent-onset disease. Pulmonary hemorrhage is an independent indication for plasma exchange. Treatment of Goodpasture's disease is discussed further in Chapter 23.

Small-Vessel Vasculitis

The majority of patients with rapidly progressive glomerulonephritis (RPGN), other than anti-GBM disease, have small-vessel vasculitis with ANCA detectable in their serum, and there is increasing evidence that these autoantibodies are pathogenic (see Chapter 24). Plasma exchange was initially introduced in such patients because of the similarity of the histologic changes to those seen in Goodpasture's disease and the supposition that immune complexes may be instrumental in disease pathogenesis. Several trials of plasma exchange in non-anti-GBM RPGN have been reported.^{7,11} Most of the early trials included patients with a variety of diseases, used a low intensity of plasma exchange, and often excluded those with oligoanuria. These trials showed no overall benefit of plasma exchange in addition to conventional immunosuppression; however, those patients with the most

Conditions for Which There is Some Evidence for the Benefit of Plasma exchange					
Indication	Randomized Controlled Trial (no. of patients)	Controlled Trial (no. of patients)	Case Series (no. of patients)	Replacement Fluid	Comments
Catastrophic antiphospholipid antibody syndrome	0	0	(280)	Plasma	Should be done daily Combination of plasma exchange or IVIG, heparin, and corticosteroids (from registry data) gives best outcomes
Primary or recurrent FSGS	0	0	40 (98)	Albumin	Sometimes in combination with cyclophosphamide May be more effective in recurrent disease after transplantation May need long-term maintenance treatment
Atypical hemolytic-uremic syndrome (aHUS) or thrombotic microangiopathy	1 (35)	1 (37)	49 (>1000)	Plasma or cryo-poor plasma	Conflicting reports on benefit in aHUS but prognosis without very poor Daily plasma exchange initially but duration variable
Myeloma	5 (182)	0	6 (105)	Albumin	Daily or alternate daily for 7–10 exchanges Despite negative randomized trial in 2005, plasma exchange should be considered if high light-chain load, severe renal failure, and oliguria despite aggressive hydration and conservative management
Rapidly progressive glomerulonephritis (may include patients with ANCA-associated disease in older literature)	7 (196)	0	20 (273)	Albumin	No good evidence for benefit in immune complex disease of any cause
Scleroderma	0	3 (75)	6 (60)	Albumin	No good evidence for benefit, but some patients have reported improvement with therapeutic trial of plasma exchange
SLE (not nephritis)	1 (20)	1 (4)	13 (124)	Albumin	For cerebritis, lupus-associated TTP, or pulmonary hemorrhage

Figure 95.6 Conditions for which there is some evidence for the benefit of plasma exchange. ANCA, antineutrophil cytoplasmic antibody; FSGS, focal segmental glomerulosclerosis; IVIG, intravenous immune globulin; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura.

severe disease did seem to benefit. Combining the results of the controlled trials, 31 of 42 (74%) dialysis-dependent patients treated with plasma exchange recovered renal function compared with only 8 of 25 (32%) treated with drugs alone. The most recent randomized, controlled trial (MEPEX: methylprednisolone or plasma exchange in severe ANCA-associated vasculitis) randomized 137 patients with ANCA-associated systemic vasculitis and serum creatinine concentration above 5.5 mg/dl (500 μ mol/l) to plasma exchange or intravenous methylprednisolone in addition to oral corticosteroids and cyclophosphamide¹¹; 69% of patients recovered renal function when treated with plasma exchange compared with 49% of those receiving intravenous methylprednisolone. Patients with both ANCA and anti-GBM antibodies (so-called double-positive patients) and RPGN

do not seem to respond so well to plasma exchange and rarely if ever recover renal function.¹²

Recommendation

We perform plasma exchange in patients with small-vessel vasculitis who present with severe renal failure (serum creatinine concentration above 5.5 mg/dl [\sim 500 μ mol/l] or dialysis dependent) or pulmonary hemorrhage. The regimen is shown in Figure 95.5.

Other Crescentic Glomerulonephritis

Crescent formation is a common histologic finding in a number of other patterns of glomerulonephritis (GN), including post-

infectious GN, GN associated with infective endocarditis, IgA nephropathy, membranoproliferative glomerulonephritis (MPGN), and membranous nephropathy. Patients historically were often included in studies of treatment of RPGN, and plasma exchange has been used in the treatment of a number of these conditions. More than 400 patients with such diseases have been treated with plasma exchange with no good evidence for any benefit in RPGN not due to anti-GBM disease or vasculitis.^{7,8} In crescentic IgA nephropathy, there are anecdotal reports of short-term benefit in patients with severe renal impairment, but longer term follow-up has proved disappointing.

Recommendation

We reserve plasma exchange in IgA nephropathy and other GN for patients with rapidly deteriorating renal function and extensive fresh crescents in the biopsy specimen.

Focal Segmental Glomerulosclerosis

Plasma exchange and protein A immunoadsorption have been used to treat patients with primary focal segmental glomerulosclerosis (FSGS) or recurrent disease after transplantation. The results have been less good in primary disease; less than 40% of patients achieve either partial or complete remission,^{7,8,13} and we do not recommend plasma exchange in this setting. Plasma exchange for recurrent disease is discussed later and in Chapter 104.

Hemolytic-Uremic Syndrome/Thrombotic Thrombocytopenic Purpura

In both hemolytic-uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP), endothelial activation leads to thrombotic microangiopathy, but through independent mechanisms (see Chapter 28).

Diarrhea-Associated Hemolytic-Uremic Syndrome

Childhood diarrhea-associated HUS (D⁺ HUS) is usually caused by bacterial verotoxins and has a good prognosis. Most children will recover fully with supportive care and management of fluid and electrolyte imbalance and hypertension. Two controlled trials of plasma infusion (at least 10 ml/kg daily) in childhood HUS complicated by dialysis-dependent renal failure showed no clinical benefit (as determined by hypertension, renal dysfunction, and proteinuria) in either short- or medium-term follow-up.¹⁴ There has been no study of plasma exchange in childhood D⁺ HUS. Plasma exchange and infusion have not been subjected to any controlled trials in adult D⁺ HUS, but uncontrolled observations suggest possible benefit.^{7,15}

Thrombotic Thrombocytopenic Purpura

Patients with TTP have a defective vWF-cleaving protease (ADAMTS13), an enzyme that normally degrades large vWF multimers, because of either inherited deficiency or autoantibodies directed against the protease. Accumulation of vWF multimers leads to systemic platelet activation under conditions of high shear stress (the microcirculation) and thrombosis. The rationale for plasma infusion and plasma exchange in TTP is therefore to replenish vWF-cleaving protease, to remove antibodies against it, and to remove the large vWF multimers from circulation.

The first prospective, controlled trial compared plasma infusion with plasma exchange (1 to 1.5 plasma volumes at least seven times in the first 9 days).¹⁶ All patients received aspirin and

dipyridamole. Of patients receiving plasma exchange, 47% had a platelet count above 150×10^9 cells/l and no new neurologic features, compared with only 25% of those receiving plasma infusion during the first 2 weeks. At 6 months, survival was substantially better in the plasma exchange group (50% versus 78%). More recent series using plasma exchange have reported mortality rates as low as 15%,⁷ and there may be an association of reduced early mortality with more intensive plasma exchange. Renal impairment is not an independent predictor of poor outcome in TTP and does not in itself warrant more intensive therapy. Fever, age older than 40 years, and hemoglobin level below 9 g/dl have been associated with a worse outcome. Whether FFP or its cryosupernatant fraction is better as replacement fluid remains unclear.

D⁻ Hemolytic-Uremic Syndrome

The cause of adult HUS remains unclear in most cases in which there is no clear diarrheal prodrome (D⁻ HUS; atypical HUS). Some patients have defective regulation of the complement pathway (e.g., factor H deficiency), leading to uninhibited activation of complement; in others, infections or drugs cause platelet or leukocyte activation and complement activation and consumption. Direct activation of endothelial cells may also be a cause. Plasma exchange and infusion have not been subjected to any controlled trials in adult D⁻ HUS, but uncontrolled series suggest benefit (see Chapter 28).⁷ HUS/TTP occurring after renal transplantation has also responded to plasma exchange.

Recommendation

We use plasma exchange in all adults with TTP or D⁻ HUS and perform all exchanges against FFP or cryo-poor FFP.

Systemic Lupus

Plasma exchange has been used extensively in patients with lupus. Most studies have included patients with diverse patterns of disease and often only mild renal involvement. A randomized, prospective trial could show no benefit of plasma exchange over conventional immunosuppression for renal, serologic, or clinical outcomes, in both the short and long term.¹⁷ However, patients with crescentic lupus nephritis and those with the most severe renal dysfunction (dialysis dependency) were excluded. Anecdotal evidence suggests that plasma exchange may benefit patients with crescentic glomerulonephritis, pulmonary hemorrhage, cerebral lupus, catastrophic antiphospholipid syndrome, lupus-associated TTP, or severe lupus unresponsive to conventional drugs and patients for whom cytotoxic therapy has been withdrawn because of bone marrow suppression or other toxicity. Immunoadsorption may be more successful in the severe forms of lupus nephritis. A variety of techniques have been used, including standard protein A and anti-Ig absorption, and also phenylalanine, tryptophan, and dextran sulfate ligands, all of which bind immunoglobulin, rheumatoid factors, and immune complexes to varying degrees and all of which have been reported to induce remission in patients with severe disease after failure of conventional therapy.

Recommendation

We reserve plasma exchange for lupus patients with rapidly progressive renal failure and class IV renal histology with crescents, for severe neurologic involvement and hemolysis, for those likely to suffer bone marrow suppression from cyclophosphamide, and

for those with catastrophic antiphospholipid syndrome. The treatment of lupus is further discussed in Chapter 25.

Cryoglobulinemia

In type I cryoglobulinemia, usually associated with myeloma or lymphoma, a monoclonal immunoglobulin causes hyperviscosity and cryoprecipitation. Such antibodies are easily removed by plasma exchange, often with immediate clinical benefit. Cytotoxic agents are used simultaneously to inhibit further paraprotein production. There are no controlled trials of the use of plasma exchange, but symptoms are closely related to the presence of the cryoimmunoglobulin, and hence treatment with plasma exchange appears effective.⁷

Patients with type II (mixed essential) cryoglobulinemia develop a monoclonal antibody (usually IgM) with specificity for a second, usually polyclonal, immunoglobulin. Type II cryoglobulins occur most commonly in association with lymphoma and hepatitis C virus infection. The resulting immune complexes can be deposited in the microcirculation and are particularly associated with MPGN (see Chapter 21). Plasma exchange is effective at clearing the immune complexes, although in long-term follow-up, the cryoglobulins often recur, and sustained benefit has not been clearly demonstrated. However, many of the acute features of cryoglobulinemia do resolve with plasma exchange, particularly arthralgia, skin lesions, and digital necrosis, and patients with RPGN can recover renal function. Concomitant immunosuppression with cytotoxic agents or rituximab may prevent resynthesis of the cryoproteins, although some patients require long-term intermittent plasma exchange to control symptoms. Immunosuppressive treatment should be used with caution in patients with hepatitis C virus–associated cryoglobulinemia who may respond to antiviral therapies, such as interferon and ribavirin. Cryofiltration apheresis (in which a normal plasma filter is used to separate plasma, which is then cooled to precipitate the cryoglobulin before return to the patient) selectively removes cryoglobulins, avoids large volumes of replacement fluids, and avoids deficiency of clotting factors, but it needs to be combined with immunosuppression to prevent synthesis of further cryoglobulin. Few centers currently perform this technique.

Myeloma

Plasma exchange has benefit in myeloma with either cast nephropathy or light-chain renal toxicity. Two small controlled trials performed more than 15 years ago provided conflicting results. Recently, a large prospective, controlled trial was reported in which 97 patients with myeloma and progressive acute kidney injury (creatinine $>200 \mu\text{mol/l}$ [2.3 mg/dl] with an increase $>50 \mu\text{mol/l}$ during the previous 2 weeks despite conventional management) were randomized to receive plasma exchange (five to seven sessions of 50 ml/kg during 10 days) in addition to chemotherapy (vincristine-doxorubicin-dexamethasone [VAD] or melphalan and prednisolone).¹⁸ This study showed no benefit of plasma exchange on mortality or recovery of renal function. However, patients had a wide degree of renal dysfunction, and relatively few had a renal biopsy performed to confirm cast nephropathy. A retrospective review from the Mayo Clinic suggested that those with myeloma and high light-chain loads or severe renal failure may benefit if plasma exchange reduced light chains rapidly.¹⁹ Promising early data suggest that hemodialysis with novel membranes allowing the removal of large-molecular-

weight molecules and lengthy dialysis sessions (6 to 8 hours) may prove superior to plasma exchange in removing light chains and improving renal function (see Chapter 63).

Recommendation

We reserve plasma exchange in myeloma for patients with high light-chain loads and cast nephropathy on biopsy.

Transplantation

Antibody-Mediated Rejection

Studies in the 1980s suggested that combining plasma exchange with cyclophosphamide could deplete circulating antibodies in patients with vascular or antibody-mediated rejection, but a review of 157 patients included in five trials could not demonstrate any significant difference in the outcome of acute vascular rejection in patients treated with or without plasma exchange.^{7,8} More recently, at least eight trials including more than 300 patients with more clearly defined antibody-mediated rejection and case series of more than 400 patients have suggested that plasma exchange, usually combined with intravenous immune globulin but sometimes antithymocyte globulin, may effectively reverse such rejection episodes in 55% to 100% of episodes.⁷

There is no convincing evidence that plasma exchange has any role in the treatment of chronic rejection.

Anti-HLA Antibodies

Highly sensitized patients with preformed anti-HLA antibodies have been treated both before and after transplantation with plasma exchange or immunoadsorption to reduce cytotoxic antibody levels.⁷ Patients usually received intensive immunoadsorption or plasma exchange before transplantation to ensure a current negative crossmatch immediately before transplantation; some received longer term immunoadsorption or plasma exchange in combination with corticosteroids and cyclophosphamide in the months preceding transplantation. Treatment of 100 patients with high-titer cytotoxic antibodies with plasma exchange or immunoadsorption in addition to cyclophosphamide and prednisolone led to graft survival rates at 1 and 4 years of 77% and 64%, respectively, in living donor recipients, and 70% and 57%, respectively, in first deceased donor graft recipients.

ABO-Incompatible Renal Transplantation

Plasma exchange is widely used to remove natural anti-A or anti-B blood group antibodies from the recipient before living related transplantation from an ABO-incompatible donor. Various protocols are in use, but all rely on depleting specific antibody during 4 to 6 days before transplantation by exchanging a single plasma volume for human albumin solution (in addition to routine immunosuppression, sometimes including rituximab and intravenous immune globulin). Plasma exchange is sometimes continued for one or two sessions after transplantation or if antibody-mediated rejection occurs.²⁰ One-year graft survival rates of up to 85% have been reported with such protocols, although rejection episodes are more common than in ABO-compatible transplants. Patients with increasingly high antibody titers are being treated in this way. More recently, immunoadsorption using synthetic A- or B-oligosaccharide epitopes linked to Sepharose has been developed. Such columns specifically remove anti-A or anti-B antibodies, but any clinical benefit remains uncertain.

Recurrent Focal Segmental Glomerulosclerosis

Plasma exchange, double filtration plasmapheresis, and protein A immunoadsorption have all been used to treat recurrence of nephrotic syndrome after transplantation in patients with recurrent FSGS.^{7,21} An incompletely defined circulating factor causing increased permeability of glomerular capillaries can be found in most patients with recurrent FSGS. There are no controlled trials of plasma treatments in recurrent FSGS, and most series are small. One study demonstrated an 82% reduction in urinary protein excretion in eight patients with recurrent nephrosis during plasma protein adsorption; however, the effect was transient and persisted for less than 2 months in seven of the eight patients.²¹ Other investigators have obtained remissions in approximately 50% of patients and a significant reduction in graft loss due to recurrent disease compared with historic controls. More intensive treatment regimens have led to more persistent remissions. All three apheresis modalities have also been used prophylactically in patients deemed to be at high risk of recurrence, with variable success. Management of recurrent FSGS is discussed further in Chapter 104.

Immunologic Principles in Kidney Transplantation

Karl Womer, Hamid Rabb

The human immune system has evolved into a complex and highly sophisticated defense mechanism against the invasion of foreign pathogens and the growth of tumor cells. Important to an effective immune response is the ability of T cells to recognize a wide variety of non-self antigens, which allows restrained immune activation and subsequent antigen-specific killing. This task is accomplished through the generation of a diverse repertoire of T cells in a single individual with specificity for an enormous number of potential foreign antigens presented as peptides on the surface of major histocompatibility complex (MHC) molecules. Variations in MHC structure from individual to individual increase the variety of peptides that can be presented to T cells, which protects the species as a group by ensuring adequate T-cell responses to a given foreign organism in at least one member of the population. Although slight, these MHC polymorphisms are recognized as foreign after kidney transplantation between nongenetically identical humans and induce alloresponses that in the absence of immunosuppression result in rejection of the allograft (see Fig. 96.1 for graft terminology). In this chapter, we review basic immunologic principles important to the field of kidney transplantation.

ISCHEMIA-REPERFUSION INJURY

The immunologic responses that occur after kidney transplantation are a series of relatively well defined stages, as depicted in Figure 96.2. Initial insults to the graft occur during donor organ procurement and subsequent transplantation into the recipient and are referred to as ischemia-reperfusion injury (IRI). The pathogenesis of IRI represents a complex interplay between biochemical, cellular, vascular endothelial, and tissue-specific factors, with inflammation as a common feature.¹ Acute ischemia leads to tissue damage and endothelial cell activation, with production of oxygen free radicals, secretion of inflammatory cytokines and chemokines, and upregulation of adhesion molecules that are important initiators of the innate or antigen-nonspecific immune response. Toll-like receptors (TLRs) are primarily expressed on resident antigen-presenting cells (APCs), mostly dendritic cells (DCs), but also on endothelial and stromal cells. Activation of TLRs by noninfectious stimuli during IRI leads to release of cytokines, including tumor necrosis factor α (TNF- α) and interleukin-6 (IL-6). These proinflammatory mediators induce tubular epithelial cell production of the chemokine CXCL8 (IL-8), which attracts neutrophils by activation of their surface chemokine receptor, CXCR2. Neutrophil accumulation is the prime cellular mediator of microvascular plugging and local tissue destruction in IRI. However, monocyte-macrophage infiltration also occurs during IRI and probably contributes to extension of early injury as well as repair.² TLR activation

induces the maturation of DCs, which leads to the adaptive or antigen-specific phase of transplantation immunity. Natural killer (NK) cells probably also function as a bridge between innate and adaptive immunity in IRI, in part through bidirectional crosstalk between NK cells and DCs, which plays a relevant role in the mechanisms leading to maturation of DCs.³ Likewise, although activation of the alternative pathway of complement plays an important role in IRI as a manifestation of the innate immune system, complement may also regulate adaptive immune responses. Whereas both T and B cells constitute the primary arms of the adaptive immune response, they also play an important role in the acute and possibly healing phases of IRI.¹ The immunologic events described are not specific to allografts, as they also occur in syngeneic grafts.

ANTIGEN PRESENTATION

Antigen-Presenting Cells

APCs are specialized cells capable of activating T cells. Antigen is endocytosed by APCs and then displayed by MHC molecules on their surface. T cells recognize and interact with the antigen:MHC complex to become activated. DCs, macrophages, and B cells are all considered “professional APCs,” although DCs are the most potent at antigen presentation. Alloimmune responses are initiated by activation of APCs (mostly DCs) through innate immune recognition systems, as described previously. DCs are highly versatile cells, determining whether the environment indicates that antigen should lead to an immune response or, alternatively, tolerance.⁴ In the graft and surrounding tissues after transplantation, DCs of either donor or host origin become activated and move to T-cell areas of secondary lymphoid organs (SLOs). The trafficking pattern of naive T cells is restricted to SLOs, such as the lymph node and spleen, but also possibly tertiary lymphoid structures formed in tissues after inflammation.⁵ They traverse from blood to lymphoid organs, where they pass through the T-cell areas and become activated on encounter of donor antigen (alloantigen) presented by activated DCs in the context of MHC molecules. Thus, the movement of DCs and naive T cells is coordinated to bring them into contact in the T-cell areas of SLOs, which appears essential for effective priming.⁶ Once activated, T cells are able to leave SLOs through lymph vessels to enter the blood and ultimately peripheral tissues, particularly into sites of inflammation. B cells are activated when antigen engages their antigen receptors, initially in the border of T-cell and B-cell areas of SLOs, where helper T-cell function is provided.⁷

Antigen-experienced memory cells may be activated by other APCs, such as graft endothelium.⁸ Patients normally have no

Figure 96.1 Graft terminology.

Graft Terminology
Autograft (autologous graft): A graft from one part of the body to another. Examples include skin and vascular grafts. No rejection occurs.
Isograft (isogenic or syngeneic graft): A graft from one member of a species to a genetically identical member of the same species. Examples include grafts between identical twins; or members of the same inbred rodent strain. No rejection typically occurs.
Allograft (allogeneic graft): A graft between nonidentical members of the same species. Examples include grafts between unrelated or related nonidentical humans; or members of different inbred rodent strains. Rejection occurs by lymphocytes reactive to alloantigens on the graft (i.e., alloresponse).
Xenografts (xenogeneic graft): A graft between members of different species. Examples include pig or baboon to human; or rat to mouse. Rejection occurs by lymphocytes reactive to xenoantigen on the graft (i.e., xenoresponse).

preexisting immunoreactivity to alloantigen unless they have been exposed to alloantigen through pregnancy, blood transfusion, or prior transplantation. However, viral antigens that cross-react with alloantigens can lead to the generation of alloantigen-specific memory cells through a process termed heterologous immunity.⁹

T-Cell Ontogeny and MHC Specificity

Allografts induce alloimmune responses due to the recognition of non-self antigens (e.g., MHC) from the graft by recipient T cells. During T-cell ontogeny, multilineage bone marrow precursors migrate to the thymus, where ultimate rearrangement of the T-cell receptor (TCR) gene occurs, resulting in irrevocable T-cell commitment. TCR gene rearrangement is random and ensures that a diverse repertoire of T cells exists to be able to respond to the enormous number of potential foreign antigens.¹⁰ The mature T-cell repertoire is determined in the thymus by two processes, positive and negative selection. Positive selection is dependent on a certain degree of antigen-specific T-cell affinity to self MHC molecules on thymic cortical epithelial cells. This process ensures that mature T cells will interact effectively with MHC to allow recognition of foreign antigen in the context of self MHC. Negative selection occurs by deletion of T cells with high affinity for self peptide and MHC, thereby preventing release of high-affinity T cells with autoimmune potential.

Mature T cells expressing their clone-specific TCRs then exit the thymus as either CD4 or CD8 T cells. The TCRs of CD4 T cells (also called helper T cells) are selected to interact with class II MHC molecules; the TCRs of CD8 T cells (precursors of cytotoxic T lymphocytes or CTLs) interact with class I MHC molecules. A fundamental principle of immunology is that T cells do not recognize intact foreign proteins directly but instead as peptides presented by self MHC on APCs. However, allelic variation among MHC molecules from individual to individual is quite small, resulting in similarities between donor and recipient MHC structure. Thus, unique to the transplant setting, recipient TCRs have a strong affinity for intact donor MHC molecules and can recognize them directly, which explains in large part the high proportion of T cells responding to alloantigen.¹¹ In fact, roughly 1/10⁵ to 1/10⁶ T cells will respond to any given nominal antigen (e.g., peptide derived from tetanus toxin or influenza hemagglutinin). However, the frequency of T cells that respond to foreign MHC molecules (alloantigens) is much higher (up to 5% to 10% of all T cells).

Pathways of Allorecognition

Recipient T cells may encounter alloantigen by either the direct or indirect pathway of allorecognition (Fig. 96.3). As previously alluded to, direct antigen presentation involves recipient T-cell recognition of donor MHC peptides in the context of intact donor MHC molecules on the surface of donor APCs. By this mechanism, donor APCs migrate from the graft to recipient lymphoid organs and activate alloreactive recipient T cells to initiate the alloimmune response. It has been suggested that the direct pathway may be particularly active early after transplantation, when a large number of donor APCs are present in the allograft. However, direct antigen presentation may also occur when recipient T cells recognize intact donor MHC molecules on cells of the graft (e.g., endothelium). B cells also recognize intact donor MHC antigen through their B-cell receptors. The best evidence of direct allorecognition is the strong *in vitro* response generated in the mixed lymphocyte reaction, in which lymphocytes are cultured with allogeneic APCs.

Indirect antigen recognition is the physiologic mechanism of foreign antigen presentation. Foreign antigen is taken up by APCs, processed intracellularly, and then presented as peptides on MHC molecules. During indirect allorecognition, donor MHC molecules are shed from the graft and processed by recipient APCs, where they are presented as peptides to recipient T cells in the context of recipient MHC molecules.¹² As donor MHC molecules are continually shed from the graft and presented by recipient APCs, indirect allorecognition may play a larger role in the late alloresponse, including chronic rejection. Indirect allorecognition may also be necessary for effective allo-antibody production and isotype switching after transplantation.¹³ Although the true relative contribution of direct versus indirect allorecognition to the alloresponse and transplant rejection remains open to question, recent work using transgenic T cells recognizing allo-MHC either directly or indirectly indicates that the direct alloresponse is short-lived, whereas the indirect alloresponse eventually becomes the driving force behind the rejection process, at least for CD4 T cells.¹⁴

Major Histocompatibility Complex

Class I and class II MHC molecules are designed for presentation of antigen from different sources for different purposes. The class I system is designed to sample cytosolic proteins to detect tumors or intracellular pathogens, such as virus and intracellular

Figure 96.2 Generation of alloimmune responses. Immunologic responses after renal transplantation represent a series of well-defined stages that result in rejection of the allograft in the absence of exogenous immunosuppression. Graft damage that follows ischemia-reperfusion injury during procurement and transplantation activates innate (antigen-nonspecific) immune responses, which recruit inflammatory cells and initiate adaptive (antigen-specific) immune responses. After activation, dendritic cells (DCs) of donor (direct pathway) or recipient (indirect pathway) origin migrate to secondary lymphoid organs (SLO), where they present alloantigen to T cells through MHC structures on their cell surface. After T-cell receptor (TCR) signaling and appropriate costimulation, T cells become activated to produce large amounts of cytokine and undergo clonal expansion. CD4 T cells provide help to B cells, CD8 T cells, and macrophages for the production of alloantibody, cellular cytotoxicity, and delayed-type hypersensitivity (DTH) responses, respectively. These effector functions result in destruction of the graft by acute rejection (AR), which may be T cell or antibody mediated.

Figure 96.3 Direct and indirect antigen presentation. In direct allorecognition, donor antigen (shown in red) is presented to recipient T cells as a peptide in the context of intact donor major histocompatibility complex (MHC) molecules on the surface of donor antigen-presenting cells (APCs). In indirect allorecognition, the donor antigen is processed by recipient APCs and presented as a peptide in the context of recipient MHC molecules.

bacteria. Class I proteins are recognized by CD8 T cells and thus provide a surveillance mechanism to target infected or malignant cells for destruction by CTLs. The class II system is designed to sample extracellular proteins that have been taken up and processed by APCs. Class II proteins are recognized by CD4 T helper cells and allow the generation of immune responses to invading pathogens that are phagocytosed by APCs. Cross-presentation is a process by which certain APCs take up, process, and present extracellular antigen on class I molecules to CD8 T cells.¹⁵ This mechanism is necessary for immunity against tumors and viruses that do not infect APCs. MHC products also play other important roles, including the positive and negative selection of developing T cells, stimulation of naive T cells that is necessary for their survival (homeostatic proliferation), induction of T-cell tolerance and anergy, tumor surveillance, and interaction with NK cells and other inhibitory or activating receptors.

The MHC gene locus (in humans, HLA) maps to a 3.5-million base pair region on the short arm of chromosome 6 and is divided into three regions: the class II region, the class III region, and the class I region. Only the class I and class II regions encode proteins involved in antigen presentation. The key MHC genes are the class I genes (HLA-A, HLA-B, and HLA-C) and the class II genes (HLA-DP, HLA-DQ, and HLA-DR). The class I and class II proteins share overall structural homology but are functionally different.¹⁶

MHC class I molecules are single polypeptide chains of 45-kd noncovalently associated with a smaller 12-kd protein, β_2 -microglobulin (Fig. 96.4). The class I heavy chain consists of three α domains (α_1 , α_2 , and α_3) and a short cytoplasmic tail. The membrane proximal α_3 domain and β_2 -microglobulin are immunoglobulin domains and serve as a membrane anchor. The

Figure 96.4 Structures of MHC class I and II. MHC class I is composed of a heavy chain divided into $\alpha 1$, $\alpha 2$, and $\alpha 3$ domains noncovalently associated with $\beta 2$ -microglobulin ($\beta 2m$). The $\alpha 1$ and $\alpha 2$ domains each form a long α helix and β sheet to make up the floor and walls of the peptide binding groove (peptide indicated by red ribbon). MHC class II is a dimer composed of α and β chains. Each chain is divided into two domains, with $\alpha 1$ and $\beta 1$ domains forming the two α helices and β pleated sheet that surround the peptide binding groove.

$\alpha 1$ and $\alpha 2$ domains are sheet-and-helix domains, each constructed to form a long α helix and an antiparallel β sheet. The two sheet-and-helix domains assemble face to face to form a long β sheet bounded by two α helices, making up the peptide binding groove. This groove can hold peptides of 8 to 10 amino acids.¹⁷

Class II proteins are heterodimers of α and β chains, each spanning the membrane.¹⁸ The $\alpha 2$ and $\beta 2$ domains are adjacent to the cell membranes and are immunoglobulin domains; the peptide binding groove is composed of the $\alpha 1$ and $\beta 1$ domains (see Fig. 96.4). The structural elements of class II are two α helices, a β pleated sheet, and two membrane proximal immunoglobulin domains, with two membrane anchors. The class II peptide binding groove is open on both ends, which accommodates larger peptides of 10 to 30 amino acids, although longer peptides are likely trimmed by peptidases to a length of 13 to 17 amino acids in most cases.

Class I proteins are expressed on virtually all nucleated cells, although the amount expressed varies. Class II proteins have a

more restricted cell distribution, generally limited to bone marrow-derived “professional” APCs, including DCs, B cells, macrophages, and Langerhans cells, but also other cells, including renal parenchymal cells, endothelial cells, Kupffer cells, thymic epithelial cells, and alveolar type II lining cells. Both class I and class II antigens can be induced on a variety of cells by interferon- γ (IFN- γ) in synergy with other cytokines.

HLA Typing and Transplantation

MHC class I and class II genes are highly polymorphic in the regions that encode the peptide binding groove. These polymorphisms help ensure survival of the population by increasing the variety of peptides that can be presented to T cells. Thus, MHC polymorphisms decrease the chance of encountering pathogens that may induce poor immune responses within a population, leading to the demise of the species.¹⁹ However, it is also these polymorphisms that predispose to allograft rejection because the antigen-presenting structures of one individual are regarded as foreign by another nonidentical individual.

Polymorphisms were originally defined by HLA serologic (antibody) typing with use of sera from multiparous women or persons who had received blood transfusions. The development of molecular biology techniques (polymerase chain reaction [PCR] sequencing) has allowed the analysis of the HLA allelic sequence diversity at the DNA level. By DNA typing, many more polymorphisms have been identified: currently 733 for HLA-A, 1115 for HLA-B, 392 for HLA-C, and 700 for HLA-DR, with around 450 new sequences added each year. The most currently updated source for HLA alleles can be identified at the website <http://www.ebi.ac.uk/imgt/bla>. Although PCR techniques allow rapid DNA sequence-based typing of human populations, serologic methods are still often used for identifying HLA antigens in kidney transplantation.

HLA Inheritance

HLA genes are inherited in a mendelian codominant fashion, meaning that a copy of each HLA gene (i.e., one haplotype) is inherited from each parent and expressed as antigens. HLA typing identifies the specific alleles carried by a person. The term *HLA matching* means assignment of a donor kidney to a recipient with as few mismatches as possible. In kidney transplantation, efforts are made to match HLA-A, HLA-B, and HLA-DR genes and proteins. It can be predicted that siblings from the same set of parents will have a 25% chance of having zero mismatches, 50% chance of having one mismatch, and 25% chance of having two mismatches (Fig. 96.5).

Non-MHC Antigens

Minor histocompatibility antigens are normal proteins that are themselves polymorphic in a given population. Even when a transplant donor and recipient are identical with regard to MHC genes, amino acid differences in these minor proteins can lead to rejection. Minor antigens are encoded by a large number of chromosomes and are presented only as peptides in the context of recipient MHC (indirect allorecognition). Minor antigens are responsible for the need for immunosuppression after donation between HLA-matched nonidentical twin siblings. The prototypic minor histocompatibility antigen, the male or H-Y antigen, is derived from a group of proteins encoded on the Y chromosome. Alloresponses to this antigen may explain reduced

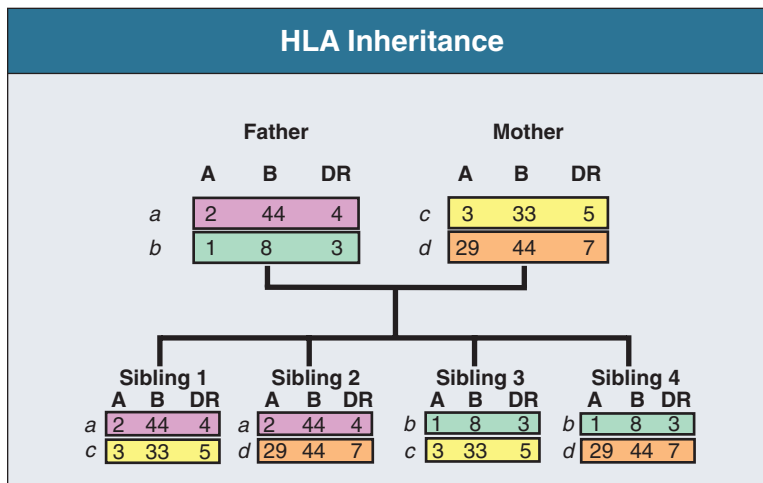

Figure 96.5 HLA inheritance. HLA antigens are inherited and expressed in a mendelian codominant fashion, whereby one copy of each HLA gene, called a haplotype (e.g., *a*, *b*, *c*, *d*), is inherited from each parent. Efforts are made to match both class I (HLA-A and HLA-B) and class II (HLA-DR) antigens.

long-term graft survival observed in male-to-female donations. MHC I-related chain A (MICA) antigens are surface glycoproteins with functions related to innate immunity. Exposure to allogeneic MICA during transplantation can elicit antibody formation.²⁰ ABO blood group glycolipids expressed on endothelial and red blood cells are other notable non-MHC antigens. Finally, immune responses to autoantigens have been associated with allograft damage.²¹

T-CELL ACTIVATION

T cells are required for rejection because animals experimentally deprived of T cells through mutation or genetic manipulation are unable to reject allografts. Alloreactive T cells can be found in the naive and memory T-cell populations, but both require recognition of non-self MHC molecules to become activated. Reactions mediated by naive T cells take longer to develop than those mediated by memory T cells, which can be generated more quickly and with higher numbers of cells (secondary response). During allograft rejection, both populations are activated simultaneously.

T-Cell Receptor

Each T cell bears about 30,000 identical antigen receptor molecules. Each receptor consists of two different polypeptide chains, termed the TCR α and β chains, which are linked by a disulfide bond. The genes encoding the TCR chains are members of the immunoglobulin supergene family, which are found on B, T, and NK cells. The α : β heterodimers are very similar in structure to the Fab fragment of an immunoglobulin molecule and account for antigen recognition by most T cells (Fig. 96.6). In contrast to the immunoglobulin receptors of B cells, TCRs do not recognize antigen in its native state but instead recognize a composite ligand of a peptide bound to an MHC molecule. A minority of T cells bears an alternative but structurally similar receptor composed of a different polypeptide heterodimer (γ : δ). These γ : δ TCRs seem to have different antigen recognition properties, although their function during alloimmune responses is not known.

Both chains of the TCR have an amino-terminal (V) domain with homology to an immunoglobulin V domain, a constant (C) domain with homology to an immunoglobulin C domain, and a

Figure 96.6 T-cell receptor complex:MHC interaction. Each T-cell receptor (TCR) consists of an α and β chain linked by a disulfide bond. The α : β heterodimers are similar in structure to the Fab fragment of an immunoglobulin molecule (see Fig. 96.9), including variable (V) and constant (C) regions. Diversity in the T-cell repertoire is encoded in the V domains of the α and β chains in three complementarity-determining regions that form the antigen binding site at the end of the TCR (*high-lighted in red*). CD8 is a disulfide-linked α : β heterodimer or α : α homodimer, with each chain containing a single immunoglobulin-like domain linked to the membrane by a polypeptide chain. CD8 binds to the conserved region of the α 3 domain of the class I MHC molecule on antigen-presenting cells (APCs) but also interacts with the class I MHC α 2 domain, probably through the α chain. CD4 is composed of four immunoglobulin-like domains and binds to a conserved site on the β 2 domain of the class II MHC molecule on APCs. Triggering of the TCR by antigen initiates a signaling cascade started by the signaling complex made up of CD3 γ , ϵ , and δ chains as well as the ζ chain homodimer.

short hinge region containing a cysteine residue that forms the interchain disulfide bond. Each chain spans the cell membrane by a hydrophobic transmembrane domain and ends in a short cytoplasmic tail. The diversity in the TCR repertoire is encoded in the V domains of the α and β chains. These V domains have three hypervariable loops or complementarity-determining regions that form the antigen binding site at the end of the TCR, interacting with the sheet-and-helix domains of the MHC molecule and the presented peptide. This interaction enhances the specificity of antigen recognition by T cells because the most variable of the complementarity-determining regions interacts with the diverse peptides presented in the MHC complex.

CD4 and CD8 Coreceptors

T cells fall into two major classes with different effector functions, distinguished by the expression of the cell surface proteins CD4 and CD8. CD4 is a single-chain molecule composed of four immunoglobulin-like domains and binds to a conserved site on the β 2 domain of the class II MHC molecule well away from the site where the TCR binds (see Fig. 96.6). CD8 is a disulfide-linked α : β heterodimer or α : α homodimer, with each chain containing a single immunoglobulin like domain linked to the membrane by a polypeptide chain. CD8 binds to the conserved region of the α 3 domain of the class I MHC molecule, equivalent to where CD4 binds class II MHC, but also interacts with the class I MHC α 2 domain, probably through the α chain. Both CD4 and CD8 have a cytoplasmic tail that can associate with signaling proteins important in T-cell activation. CD4 and CD8 binding to MHC are required to make an effective response. Thus, these molecules are called coreceptors.

T-Cell Receptor Engagement of Antigen: Signal 1

The TCR α : β heterodimer recognizes and binds its peptide:MHC ligand²² but cannot signal to the cell that antigen has bound. In the functional receptor complex, α : β heterodimers are associated with a complex of four other signaling chains (two ϵ , one δ , one γ) collectively called CD3. The cell surface receptor is also associated with a homodimer of ζ chains (see Fig. 96.6).

Engagement of the TCR by MHC, along with the other required receptor engagements, initiates the signaling process from the CD3 complex.²³ The first event is activation of the protein kinase Lck, which is associated with CD4 or CD8 molecules. Activated Lck phosphorylates tyrosine residues on the CD3 molecules that then serve as anchoring sites for the protein tyrosine kinase ZAP-70. ZAP-70 phosphorylates several downstream substrates, including adaptor and linker molecules, which leads to activation of phospholipase C (PLC- γ) and the Ras-MAP kinase pathway. PLC- γ cleaves phosphatidylinositol bisphosphate to yield diacylglycerol (DAG) and inositol triphosphate (IP₃). DAG activates protein kinase C, leading to activation of the nuclear factor κ B (NF- κ B) pathway. IP₃ acts on the endoplasmic reticulum to induce the release of intracellular Ca²⁺, which leads to activation of the protein-serine phosphatase calcineurin. Calcineurin dephosphorylates the transcription factor nuclear factor of activated T cells (NF-AT), allowing it to translocate into the nucleus. Translocation of NF-AT and NF- κ B, along with activator protein 1 (AP-1) activated by the Ras-induced kinase cascade, allows the transcription of the genes for IL-2 and other cytokines as well as the genes for the high-affinity subunit of the IL-2 receptor (CD25), leading to cell proliferation and differentiation.

T-Cell Costimulation: Signal 2

Binding of the TCR:CD3 complex to the peptide:MHC class II complex on APCs delivers a signal that can induce the clonal expansion of naive T cells only when the appropriate costimulatory signal is delivered (signal 2). CD8 T cells require a stronger costimulatory signal, and their clonal expansion is aided by CD4 T cells interacting with the same APC (i.e., T helper function). Costimulation is likely a checkpoint developed by the immune system to prevent the activation of self-reactive T cells that escaped negative selection in the thymus. Antigen binding to the TCR in the absence of costimulation not only fails to activate the T cell but leads to a state called anergy, in which T cells become refractory to subsequent activation or even undergo apoptosis (programmed cell death). Thus, costimulation removes this inhibition and determines whether a T cell will proceed with clonal expansion and the development of effector functions. It is now clear that costimulatory molecules can provide positive or negative signals to T cells (Fig. 96.7). Thus, it is the integration of both positive and negative costimulatory signals during and after initial T-cell activation, dictated by their temporal and spatial expression patterns, that ultimately determines the fate and functional status of the T-cell response.²⁴ In transplant models, rejection can occur when costimulatory molecules are absent from the donor APCs and MHC class II is absent from the recipient APCs, suggesting that bystander APCs can provide trans-costimulation.²⁵

CD28 and its ligands B7.1 (CD80) and B7.2 (CD86) are the best characterized costimulatory molecules and are members of the immunoglobulin superfamily.²⁶ CD28 is constitutively expressed on all naive CD4 and CD8 T cells. However, a significant proportion of memory T cells, especially memory CD8 T cells, are CD28 negative. Ligation of CD28 by B7 molecules is required for clonal expansion of naive CD4 T helper cells. Once activated, T cells express increased levels of CTLA-4 (CD152). CTLA-4 has a higher affinity than CD28 for B7 molecules and thus binds most or all of the B7 molecules, effectively shutting down the proliferative phase of the response. This effect can also be achieved by the administration of CTLA-4Ig, a fusion protein with high affinity for B7 molecules. B and T lymphocyte attenuator (BTLA) and programmed death 1 (PD-1) are two other costimulatory molecules of the immunoglobulin superfamily that, when engaged by their ligands (HVEM and PD-L1/PD-L2, respectively), provide inhibitory signals to T cells.

Activated T cells express a number of proteins that contribute to sustainment or modification of the costimulatory signal to drive clonal expansion and differentiation. The inducible costimulatory molecule (ICOS) is a CD28 homologue, but unlike CD28, it is not constitutively expressed on naive T cells. Rather, ICOS is induced only after T-cell activation. The ligand for ICOS is B7H (also called ICOS-L, B7RP-1, B7H-2, and GL-50), and although it is structurally related to B7 molecules, it does not bind to either CD28 or CTLA-4. Engagement of ICOS by B7H enhances T-cell proliferation, cytokine production, and survival. ICOS is also expressed on B cells and provides help for antibody production by activated B cells. Finally, ICOS is expressed on memory T cells and FOXP3⁺ T regulatory cells (Tregs).

Costimulatory molecules of the TNF and TNF-R superfamily include CD40 ligand (CD40L, CD154) on T cells and its receptor CD40 on APCs, such as B cells, DCs, macrophages, and endothelial cells. Binding of CD40 by CD40L transmits

Figure 96.7 T-cell costimulation.

activating signals to the T cell but also activates the APCs to secrete proinflammatory molecules and to express B7 molecules, thus stimulating further T-cell proliferation. Engagement of CD40 on DCs by T helper cells allows proper priming of precursor CTLs. CD40 ligation on B cells promotes their survival and proliferation and induces class switching, allowing the production and secretion of specialized, higher affinity antibodies. Costimulatory molecules of the TNF:TNF-R superfamily include many other receptor-ligand pairs and, with the exception of CD27, are expressed only on T-cell activation.²⁶ This finding has given rise to the general view that costimulatory molecules in this family are more important for the effector and memory phases of the immune response rather than for the initial phase of T-cell priming.

TIM (T-cell immunoglobulin and mucin domain) molecules are type I transmembrane glycoproteins that like other molecules in this family consist of an extracellular domain, a transmembrane domain, and a cytoplasmic domain. The extracellular domain of all TIM molecules contains an immunoglobulin V motif and a heavily glycosylated mucin motif, a structural feature that distinguishes this family member from other costimulatory molecules. Similar to other costimulatory molecules, however, the cytoplasmic domain contains a tyrosine phosphorylation motif that is involved in signal transduction on ligand binding. The human TIM gene family has three members (TIM-1, TIM-3, and TIM-4) and is involved in regulating a wide array of immune-related responses that are not yet fully understood.

T-Cell Clonal Expansion and Differentiation

In most instances, the number of T cells that react to a given antigen is quite small. Therefore, effective immune responses generally require clonal expansion and differentiation of T cells. These processes are largely driven by cytokines, including IL-2, which acts on the T cell in an autocrine fashion or by paracrine secretion to neighboring T cells. Activated T cells produce the α subunit of the IL-2 receptor (IL-2R or CD25), enabling a fully functional signaling receptor composed of α , β , and γ subunits that can bind IL-2 with high affinity, which in turn activates T-cell proliferation pathways. The list of cytokines is large and continues to grow. Figure 96.8 lists selected cytokines involved in allograft rejection, their sources, and their effects.

CD4 and CD8 T cells have different roles during immune responses. CD4 T cells are both effectors and regulators and are notable for heavy cytokine secretion. After prolonged stimulation, CD4 T cells sometimes tend to express groups of several cytokines, probably depending on the local environment, the nature of the antigen, and the type and activation status of the APC. The so-called Th1 (for T helper 1) clones produce IL-2, IFN- γ , and lymphotoxin; Th2 clones produce IL-4, IL-5, and IL-10. As the effects of these cytokines became known, it was apparent that the subdivision of production correlated with a categorization of function. Th1-derived cytokines are growth and maturation factors for CTLs (especially IL-2) and macrophages (particularly IFN- γ); Th2-derived cytokines act similarly on B cells. Rejecting allografts typically express high levels of

Figure 96.8 Cytokines involved in allograft rejection. IL, interleukin; DC, dendritic cells; EC, endothelial cells; NK, natural killer; CTL, cytotoxic T lymphocytes; Treg, regulatory T cells; Ig, immunoglobulin; AICD, activation-induced cell death; Th, T helper (cell); IFN- γ , interferon- γ ; TNF- α , tumor necrosis factor α ; TGF- β , transforming growth factor β .

Cytokines Involved in Allograft Rejection		
Cytokine	Source	Biologic activity
IL-1	Macrophages, DC, EC, NK cells	Proinflammatory, adhesion molecule expression on EC, NK cell function
IL-2	Activated T cells	T cell proliferation, CTL and NK cell function, Treg maintenance, Ig production by B cells, AICD of activated T cells
IL-4	Activated T cells	Activated T and B cell proliferation, Th2 differentiation, allergic responses, MHC II upregulation on B cells
IL-6	T cells, macrophages, EC	Proinflammatory and anti-inflammatory, acute-phase responses
IL-10	T cells, macrophages, DC	Anti-inflammatory, suppression of APC function, NK cell inhibition
IL-12	Macrophages, DC	Proinflammatory, Th1 differentiation, NK cell and CTL activity, IFN- γ and TNF- α production by NK and T cells
IL-15	Epithelial cells, stromal cells, macrophages	NK cell proliferation, T cell proliferation, memory T cell survival
IL-17	T cells	Proinflammatory and allergic responses, Th17 function, cytokine production from many cell types
IFN- γ	Activated Th1 cells, CTL, DC, NK cells	MHC expression by EC, macrophage function, Th1 differentiation, Th2 suppression, adhesion and binding of T cells to EC, NK cell activity
TGF- β	T and B cells, macrophages, platelets	Anti-inflammatory, wound healing, fibrosis
TNF- α	Macrophages, T and B cells, EC, NK cells	Proinflammatory, acute phase responses, cytotoxicity

mRNA for both subsets of cytokines and cannot be considered a pure Th1 response. T helper 17 (Th17) cells are a subset of T helper cells distinct from Th1 and Th2 clones²⁷ that produce IL-17, IL-21, and IL-22.²⁸ Th17 cells are thought to play a key role in autoimmune disease, and their role in transplantation is currently under intense investigation.

Memory Cells

Although there is limited knowledge of how memory T cells are generated or maintained, these cells are an important component of the immune response after transplantation. The principle of immunologic memory is that the immune response to a previously encountered antigen is swifter and more effective than the

response to a new antigen. Memory cells seem to be more easily activated than naive T cells and in addition produce more cytokines. Furthermore, there is an increase in antigen-specific T-cell frequency after exposure to a given antigen. Finally, exposure to antigen leads to a refinement of the antibody repertoire, resulting in a more effective memory response. Effector memory T cells are specialized to quickly enter inflamed tissues, as they can rapidly mature into effector T cells and secrete larger amounts of cytokines after restimulation. Central memory T cells probably remain in the SLOs and do not produce as much cytokine.²⁹ Memory cells are believed to persist after an initial immune response through expression of the antiapoptotic genes Bcl-2 and Bcl-xL, which are induced primarily by IL-2 and

CD28 stimulation. IL-15 may also provide survival signals. Long-term memory cell survival is likely to be a function of periodic interactions with self MHC–peptide complexes (i.e., homeostatic proliferation).

EFFECTOR FUNCTIONS

Once activated and expanded, T cells exert effector functions that result in destruction of graft tissue. Although T cells are essential for acute organ allograft rejection, the precise mechanisms by which they mediate graft injury are uncertain. CD4 T helper cells may release numerous cytokines that affect the alloimmune response. For example, they may promote delayed-type hypersensitivity (DTH) responses that involve stimulating production of nitric oxide, reactive oxygen species, and TNF- α by macrophages. T-cell cytokines may also act directly on parenchymal cells or indirectly through effects on the endothelium and vascular supply. TNF- α and TNF- β exert local cytotoxic effects on receptors on the graft, including endothelial cells (TNF-R1) and tubular cells (TNF-R2). IFN- γ , the prototypical Th1 cytokine, is released by both CD4 and CD8 T cells during rejection. IFN- γ induces MHC class II expression on endothelium and MHC class I expression on vascular endothelial cells, epithelial cells, and parenchymal cells in the graft. The precise role of class II expression by donor cells in the graft remains controversial because mouse kidney grafts lacking class II are rejected more vigorously. Although IFN- γ is strongly associated with rejection, it probably has other signaling roles that actually help to stabilize the graft. As cytokine production by CD8 T cells is generally lower than that of CD4 T cells, production of cytokines such as IL-2 by CD4 T cells provides help for the generation of CTLs from their CD8 T-cell precursors. CD4 T cells may themselves become cytolytic T cells, by mechanisms similar to those used by CD8 CTLs (described later). CD4 T cells also provide help to B cells to enhance their production of alloantibodies. Finally, Tregs may have important roles in suppressing immune responses and maintaining tolerance.

CTL Differentiation and Function

With rare exceptions, virtually all CTLs are MHC class I-restricted CD8 T cells. Activated CTLs possess two mechanisms to kill target cells that require cell-cell contact.³⁰ The first mechanism is by the release of specialized lytic granules. Perforin and granzyme B are two proteins found in granules of most CTLs and NK cells. Perforin, like complement components, has the ability to induce transmembrane pores. The granzyme B–perforin complex enters the cell through the mannose 6-phosphate receptor, and after internalization, perforin allows granzyme B to enter the cell through the vesicle surface to induce programmed cell death through apoptosis.³¹ A third cytotoxic protein, granulysin, is also able to induce apoptosis in target cells. The second mechanism is by Fas/Fas ligand (FasL) interactions. Fas (CD95) is a member of the TNF-R family and is the surface mediator of a pathway that, when activated by FasL on activated CTLs, induces the target cell to undergo apoptosis. Both pathways induce apoptosis through activation of the caspase cascade in target cells. As previously alluded to, CD8 CTLs also release several cytokines that exert direct cytotoxic effects, including IFN- γ , TNF- α , and TNF- β .³² Effector CD4 T cells that can mediate class II-restricted cytotoxicity to minor antigens have also been detected.

Macrophage Activation

The activated macrophage is an important mediator of DTH responses, which lead to localized tissue destruction. Resting macrophages must be activated to exert full inflammatory and cytopathic effects. Th1 cells provide help for this activation by interaction of CD40L with CD40 on the macrophage and by production of IFN- γ , which sensitizes the macrophage to respond to IFN- γ . It is possible that T-cell membrane-associated TNF- α and TNF- β can substitute for CD40L. CD8 T cells also produce IFN- γ and can activate macrophages. Production of TNF- α , oxygen radicals, and nitric oxide by activated macrophages is important for their cytopathic effects. Activated macrophages can also produce IL-12, which directs the differentiation of activated naive CD4 T cells into Th1 effector cells. Macrophage activation is inhibited by cytokines such as transforming growth factor β (TGF- β) and IL-10, many of which are produced by Th2 cells.

Humoral Immune Response

The extracellular spaces of the body are protected by humoral immune responses, in which antibodies produced by B cells cause the destruction of extracellular microorganisms and prevent the spread of intracellular infections. Membrane-bound immunoglobulin on the B-cell surface serves as the antigen receptor and is known as the B-cell receptor (BCR; Fig. 96.9). It is associated with antigen-nonspecific signaling molecules, Ig α and Ig β .

Figure 96.9 B-cell receptor and IgG structure. B-cell surface membrane-bound immunoglobulin M (IgM) associated with antigen-nonspecific signaling molecules, Ig α and Ig β , forms the B-cell receptor complex. The IgG molecule is made up of four polypeptide chains, comprising two identical light (L) chains (yellow) and two identical heavy (H) chains (green). Each of the four chains has a variable (V) region at its amino terminus (Fab portion), which contributes to the antigen binding site, and a constant (C) region (Fc portion), which determines the isotype. The V domains contain hypervariable regions that determine antigen specificity called complementarity-determining regions (highlighted in red).

Immunoglobulin of the same specificity is then secreted as antibody by terminally differentiated B cells (i.e., plasma cells). B cells develop in the bone marrow and undergo sequential rearrangement of immunoglobulin gene segments to generate a diverse repertoire of antigen receptors that can interact with antigen in their environment. In a process similar to that for developing T cells in the thymus, immature B cells that are strongly self-reactive at this stage are inactivated by negative selection. In contrast to T cells, new B cells are continually produced in adulthood.

B-cell activation requires binding of antigen to the BCR. Although some polysaccharides and polymeric proteins can activate B cells directly, antibody responses to most proteins require both binding of the antigen to the BCR and interaction of the B cell with antigen-specific helper T cells. Helper T cells recognize peptide fragments derived from the antigen that are internalized and presented as peptide:MHC class II complexes on the B-cell surface. Helper T cells stimulate B cells through the binding of CD40L with CD40 on B cells, through interaction of other TNF:TNF-R family ligands, as well as by the directed release of cytokines. Although these helper T cells are generally of the Th2 subset, Th1 cells can also assist with B-cell activation. Activated B cells also provide signals to T cells through B7 family molecules that promote their continued activation.

Secretion of antibodies, which bind pathogens or their toxic products, is the main effector function of B cells in adaptive immunity. The antibody molecule has two separate functions: one is to bind specifically to molecules from the pathogen that elicited the immune response; the other is to recruit other cells and molecules to destroy the pathogen bound by the antibody. The five major classes of antibodies are IgM, IgD, IgG, IgA, and IgE. IgG is by far the most abundant immunoglobulin and has several subclasses (IgG1, 2, 3, and 4). The IgG molecule is made up of four polypeptide chains, comprising two identical light (L) chains of 25-kd and two identical heavy (H) chains of 50-kd that form a flexible Y-shaped structure (see Fig. 96.9). Each of the four chains has a variable (V) region at its amino terminus (Fab portion), which contributes to the antigen binding site, and a constant (C) region (Fc portion), which determines the isotype. The V regions of a given antibody contain hypervariable segments that determine antigen specificity by forming a surface complementary to the antigen and are referred to as complementarity-determining regions.

After appropriate activation and help from T cells, previously naive B cells undergo vigorous proliferation, secrete IgM, and then undergo differentiation into memory B cells or antibody-secreting plasma cells. During this process, the antibody isotype can change (to IgA, IgG, or IgE) in response to cytokines released by helper T cells, and the antigen-binding properties of the antibody can change by somatic hypermutation of the V region genes. T helper cells selectively activate higher affinity mutants, resulting in high-affinity plasma cells and memory B cells. Antibodies can function in several different ways once bound to their target antigen. These mechanisms include fixation of complement, opsonization for phagocytosis by Fc receptor (FcR)-positive cells, opsonization for cell lysis by cells capable of antibody-dependent cellular cytotoxicity (ADCC), and induction of eosinophil degranulation.

Natural Killer Lymphocytes

NK cells, a subset of peripheral lymphocytes, share certain developmental and functional features with the more numerous CD8 T lymphocytes.³³ Unlike T or B cells, NK cells do not possess a

clonotypically distributed, antigen-specific cell surface receptor that is generated by gene recombination. Instead, NK cells use an array of receptors that recognize the loss of HLA class I molecules on susceptible targets. Peripheral NK cells are mature, do not require costimulation and differentiation as with T cells, and immediately release cytotoxic granules and inflammatory cytokines such as TNF- α and IFN- γ on detection of relevant targets. Given the strong cytolytic function and potential for autoreactivity, NK cell activity is tightly regulated. Mechanisms of activation include cytokines, binding of antibody to Fc receptors, and binding of ligands to activating and inhibitory receptors. NKG2D is an activating receptor expressed on all NK cells and NKT lymphocytes.³ The presence of NKG2D ligands, including MHC class I-related antigen, has been reported on human transplant samples undergoing acute allograft rejection and acute tubular necrosis. Thus, NKG2D ligands in the graft may stimulate a cytolytic cellular immune response after transplantation by interacting with cells bearing NKG2D, including NK cells. Recent animal models, however, have questioned whether NK cells play a significant role during rejection.³⁴

Termination of the Immune Response

To avoid massive continued expansion of the lymphoid pool, it is important to have mechanisms in place to terminate the immune response. Once the source of antigen is destroyed, there is no longer an inciting stimulus to induce further activation and proliferation of lymphocytes. However, preexisting effector cells can cause antigen-specific tissue damage and must be deactivated. Several mechanisms accomplish this task. Once they are terminally mature, DCs switch cytokine production from IL-12 to IL-10, favoring the generation of regulatory phenomena that suppress the function of effector T cells. As mentioned previously, induction of CTLA-4 after T-cell activation provides regulatory feedback to provide inhibitory signals to T cells that induce anergy. In the absence of continued cytokine production, T cells lack the necessary growth factors and undergo passive cell death. Finally, activated T cells undergo activation-induced cell death (AICD) by the expression of Fas and FasL on their surface. Engagement of Fas by its ligand triggers a death signal, leading to apoptosis of the cell. Because both molecules are expressed on the same cell, elimination of T cells can be through “suicide” as well as by “fratricide.” Although IL-2 is important for the clonal expansion of T cells, it is also essential for AICD. Finally, Tregs are important in maintaining self-tolerance after removal of effector T cells.

ALLOGRAFT REJECTION

Allograft rejection is defined as tissue injury produced by the effector mechanisms of the alloimmune response, leading to deterioration of graft function. There are two types of rejection: T cell-mediated rejection (TCMR) and antibody-mediated rejection (AMR). Both types of rejection can be early or late, fulminant or indolent, and isolated or concomitant. For the purposes of this chapter, the two types are described separately.

Recruitment of Cells into the Interstitium of Kidney Allografts

Allograft rejection is caused by several cellular elements of the immune system, including T cells, macrophages, B cells, plasma cells, eosinophils, and neutrophils. Although there are a variety

Proteins Involved in the Recruitment of Leukocytes into Allografts			
Protein type	Name	Ligand	Function
Selectins	CD62L/L-selectin	Sialated glycoproteins	Initial rolling of leukocytes on endothelium
	CD62P/P-selectin CD62E/E-selectin		
Chemokines	MCP-1/CCL2	CCR2	Recruitment of monocytes, immature DC, T cells, and NK cells
	MIP-1 α /CCL3	CCR1	Recruitment of monocytes, immature DC, T cells, and neutrophils
	RANTES/CCL5	CCR1, CCR4, CCR5	Recruitment of monocytes, DC, T cells, NK cells, and neutrophils
	IL-8/CXCL8	CXCR1, CXCR2	Recruitment of neutrophils
	MIG/CXCL9	CXCR3	Recruitment of activated memory T cells
	IP-10/CXCL10	CXCR3	Recruitment of activated memory T cells
	Lymphotactin/XCL1	XCL1	Recruitment of T cells
Immunoglobulin superfamily	CD54/ICAM-1	LFA-1	Tight adhesion of leukocytes to endothelium
	CD102/ICAM-2 CD50/ICAM-3	LFA-1	Tight adhesion of leukocytes to endothelium (not as strong as ICAM-1)
	CD106/VCAM-1	VLA-4	Rolling and tight adhesion of leukocytes to endothelium
	CD31/PECAM-1	CD31	Extravasation of leukocytes across endothelium

Figure 96.10 Proteins involved in the recruitment of leukocytes into allografts. DC, dendritic cells; ICAM, intercellular adhesion molecule; NK, natural killer; PECAM, platelet-endothelial cell adhesion molecule; VCAM, vascular adhesion molecule.

of target cells in the graft, endothelial and tubular cells are particularly affected by these mediators. T cells serve as the main effectors and regulators of the alloimmune response; macrophages serve as possible effectors but also aid in the removal of apoptotic cells. B cells and plasma cells serve in the production of alloantibodies, and neutrophils probably cause significant damage during AMR.

A three-step model has been proposed to explain the entry of cellular infiltrates into the allograft: tethering, adhesion, and transmigration. Figure 96.10 lists several of the proteins involved in this process. The endothelium of postcapillary venules in the graft serves as the entry point of recipient leukocytes from the blood stream. Selectins are constitutive and inducible lectin-like molecules on the endothelium that cause leukocytes to roll along

the vessel wall, a process called tethering. Leukocytes slowed down by selectins come into more prolonged contact with the endothelium. As a result, leukocytes are stimulated by chemokines, a group of small proinflammatory molecules produced by inflamed tissue that are fundamentally important in attraction of cells into an inflammatory infiltrate. Once they are secreted, chemokines bind locally to cell surface proteoglycans on endothelial cells, allowing them to activate leukocytes as they roll by. As chemokines bind to receptors on leukocytes, they activate the adhesion function of integrins.

Integrins are $\alpha\beta$ heterodimers formed by noncovalent association. The best characterized integrin, LFA-1, is expressed on most leukocytes. The ligands for LFA-1, including ICAM-1, ICAM-2, and ICAM-3 (immunoglobulin superfamily gene

Figure 96.11 T cell- and antibody-mediated rejection.

CD4 T cells induce epithelial and endothelial cell damage directly by secretion of cytokines but also indirectly by activation of cytotoxic T lymphocytes (CTLs) and macrophages. CTLs may cause apoptosis by releasing cytolytic granules containing granzymes and perforin or by exposure of Fas ligand (FasL) on the T-cell surface. The integrin component CD103 is postulated to help retain T cells in epithelial layers by binding to E-cadherin, expressed most strongly in the distal nephron. Macrophages induce local tissue damage through secretion of cytokines, oxygen species, and nitric oxide (delayed-type hypersensitivity response). CD4 T cells secrete cytokines, which induce upregulation of major histocompatibility complex (MHC) molecules on epithelial and endothelial cells. CD4 T cells also provide help to B cells for production of alloantibody by engagement of CD40L and production of cytokines. Anti-graft antibody is usually directed at MHC molecules, followed by activation of complement. Damaged endothelial cells secrete factors that activate coagulation systems and result in formation of microthrombi. Tubular cells chronically exposed to transforming growth factor β (TGF- β) may undergo epithelial-mesenchymal transition, an aberrant phenotype evidenced by epithelial cell expression of α -smooth muscle actin and loss of E-cadherin expression. These cells then may infiltrate the interstitium and contribute to fibrosis.

members), are expressed weakly on resting endothelium but are induced by activation with cytokines, such as IL-1 and TNF- α . Likewise, activation of leukocytes by chemokines triggers the transition of their surface LFA-1 to a high-affinity state for ICAM, resulting in tight adhesion of the leukocyte to the endothelium. This adhesion contributes to antigen recognition, and through a process called haptotaxis, leukocytes are induced to move along the vessel wall by an adhesion gradient.

Transmigration is the final step in the process of cellular entry into the allograft. Rapidly after integrin engagement of their ligands, leukocytes flatten and then undergo diapedesis through gaps between endothelial cells. Leukocyte secretion of proteases degrades the basement membrane, allowing the escape of leukocytes from the vessel. Once they are in the interstitium, secretion of metalloproteinases allows leukocytes to digest extracellular matrix to move through the tissue on a chemokine gradient by a process called chemotaxis. Confronted with foreign antigen in the allograft, previously activated T cells are capable of releasing proinflammatory cytokines (helper T cells) or of directly killing foreign cells (cytotoxic T cells). Recent work in mouse models of renal allograft rejection indicates that allorecognition by T cells occurs in perivascular sites by day 1 after allotransplantation; alloimmune parenchymal damage begins at day 3, coinciding with the emergence of T-cell and monocyte-macrophage and DC (MMDC) infiltrates; and finally tubulitis and arteritis develop by day 7.³⁴

Acute T Cell-Mediated Rejection

Tubulitis, invasion of the tubular epithelium by infiltrating T cells and myeloid cells of the MMDC series, is a characteristic feature of acute TCMR (Fig. 96.11). In fact, deterioration of

renal function during TCMR correlates with tubulitis and arterial inflammation (endothelialitis), which is much less common. Although it is generally agreed that T cells orchestrate the process that results in damage to the allograft, the precise mechanisms are not clear. As described earlier, CTLs can kill target cells by release of cytotoxic molecules (perforin, granzyme B, and granulysin) or by engagement of Fas on target cells by FasL, with both mechanisms resulting in apoptotic death of the target cell. Human gene expression studies show an increase in mRNA for CTL-associated transcripts, including granzyme B, perforin, and FasL, as well as T-bet, a master transcription factor for effector Th1 lymphocytes. Moreover, lymphocytes expressing mRNA and perforin protein are closely associated with tubular epithelial cells. Some studies suggest that tubulitis may involve a specific subset of CTLs expressing the integrin CD103, which binds to its ligand E-cadherin on epithelial cells, resulting in retention of T cells in the tubules.

Proof of mechanisms in organ transplantation, however, relies on *in vivo* models in animals. Although class I MHC-mismatched heart allografts show prolonged survival in perforin/granzyme, Fas/FasL, and CD103 knockouts indicates that any one of these individual cytolytic pathways is dispensable because acute rejection still occurs with these deficiencies in fully mismatched combinations.³⁵ These studies argue against cytotoxicity as a primary mechanism to explain graft epithelial cell deterioration. Likewise, CD103:E-cadherin interactions may not be responsible for creating the lesions of tubulitis but rather may reflect damaged cells that lose the ability to exclude inflammatory cells. Thus, tubulitis may not be the cause of tubular cell deterioration but instead a sign that has already occurred.

T cells may mediate rejection instead through the secretion of cytokines, either through direct effects of soluble products or through the ability to activate macrophages to organize a DTH response. DTH responses involve the release of reactive oxygen species, proteolytic enzymes, icosanoids, and other products. These products may act directly on tubular epithelium and interstitial matrix or indirectly by effects on endothelium and the vascular supply.

Endarteritis is detected in a minority of biopsy specimens taken for acute TCMR and often responds only to anti-T cell therapies, arguing for a pathogenic role for T cells. Endarteritis is not always associated with interstitial inflammation, arguing for a T-cell pathway distinct from that of tubulointerstitial rejection. Glomerulitis is an occasional feature of acute TCMR, and cells are typically a mixture of T cells and macrophages. Why the glomerulus becomes the target in only a minority of cases is not currently known. FOXP3⁺ CD4 Tregs are concentrated in tubules during rejection, although their role during TCMR continues to be debated.

Acute Antibody-Mediated Rejection

Acute AMR is recognized as a distinct clinicopathologic entity and may occur with or without a component of TCMR (see Fig. 96.11). Although it is typically a response to donor HLA antigens expressed on endothelial cells, AMR can occur to non-HLA antigens. Examples include ABO blood group antigens and the putative endothelial alloantigens, as suggested by the rare occurrence of AMR in HLA-identical sibling grafts. Even autoantibodies have been implicated, such as those to angiotensin II type 1 receptors. The kidney typically shows an accumulation of neutrophils and monocytes in peritubular and glomerular capillaries, although the infiltrate can be quite sparse.³⁶ Tubulitis and endarteritis are generally minimal, unless a component of TCMR is present. FOXP3⁺ Tregs are more rare in the AMR infiltrate than that of TCMR,³⁷ perhaps indicating a factor in the poorer prognosis. A subset of acute AMR that can result in immediate graft failure is hyperacute rejection, which is due to the presence of preformed anti-donor HLA antibody in sensitized recipients or of antibodies to mismatched ABO blood group loci. This type of AMR is rare now that crossmatching practices and desensitization protocols are routinely employed by transplant centers.

Alloantibodies are cytotoxic through their ability to activate complement. The classical pathway appears most relevant, as other pathways have not been shown to participate in acute or chronic AMR. C4d is an inactive fragment of C4b, an activation product of the classical pathway. C4b and C4d contain an occult sulfhydryl group that forms a covalent thioester bond with nearby proteins bound in the tissue after activation by immunoglobulin and C1. No functional role for C4d has been reported, but it remains in the tissue for several days after immunoglobulin and C1 have been released. C4d deposition is strongly associated with circulating antibody to donor HLA class I or class II antigens and is currently the best single marker of complement-fixing circulating antibodies to the endothelium.

The acute effects of complement are well described and include chemoattraction of neutrophils and macrophages through C3a and C5a, vasospasm through the release of prostaglandin E₂ from macrophages, and edema through the release of histamine from mast cells. C3a and C5a increase endothelial adhesion molecules and various cytokines and chemokines.³⁸ The membrane attack complex, C5b-9, causes lysis of endothelial cells. Alloantibodies may also induce cell damage through complement-

independent pathways by recruitment of leukocytes with FcγIRs (CD16), including NK cells and macrophages (antibody-dependent cellular cytotoxicity). Finally, antibodies without leukocyte or complement participation can activate endothelial cells to produce chemokines and to promote rejection in some animal models.³⁹

A common feature of all types of AMR is the presence of microthrombi. As a result of antibody-mediated damage, von Willebrand factor is released from the endothelium, leading to platelet aggregation.⁴⁰ Animal models indicate that clotting activation is a direct consequence of complement fixation. Activation of endothelial protease-activated receptors by coagulation proteases, including thrombin, leads to the secretion of many proinflammatory cytokines.⁴¹

Chronic Rejection

Late allograft dysfunction is due to a combination of alloimmune mechanisms (i.e., chronic rejection) and alloimmune-independent mechanisms, including hypertension, calcineurin inhibitor toxicity, and recurrent disease.⁴² Chronic rejection may occur by either cellular or humoral mechanisms, or both. Histologic features characteristic of chronic rejection are transplant glomerulopathy, peritubular capillaropathy (see later), transplant arteriopathy, and, less specifically, tubular atrophy and interstitial fibrosis.

Transplant glomerulopathy is defined by the widespread duplication or multilamination of the glomerular basement membrane (GBM), sometimes accompanied by mesangial expansion and accumulation of mononuclear cells in glomerular capillaries. GBM duplication may be caused by a number of insults to the allograft glomerulus, including recurrent or *de novo* immune complex glomerular disease and thrombotic microangiopathy. However, it is believed that chronic antibody-mediated injury predominates, as the majority of cases of transplant glomerulopathy are associated with circulating antibody to donor class II MHC antigens (sometimes class I antigens), and approximately 30% to 50% of these cases have C4d deposition in the peritubular capillaries.⁴³ It is believed that the absence of C4d deposition in the remainder of cases represents intermittent antibody involvement.

Similar to findings in transplant glomerulopathy, multilamination of peritubular capillaries can be demonstrated by electron microscopy (peritubular capillaropathy). It is believed that repeated episodes of antibody-mediated injury to the endothelium result in repair mechanisms that are characterized by duplication of the basement membrane. What leads to episodic antibody injury is unknown but may represent the fluctuating donor-specific antibody levels observed in some patients followed up longitudinally. Neointimal thickening can be observed in either C4d positive or negative chronic rejection. Known as transplant arteriopathy, this lesion is characterized histologically by thickening of the arterial intima without duplication of the elastica (in contrast to fibroelastic thickening seen in hypertension). Macrophages and T cells may sometimes be demonstrated within the thickened intima, providing evidence of cell-mediated immunologic activity.

Although it is not specific for rejection, interstitial fibrosis with tubular atrophy is another important histologic feature of chronically rejected allografts. One putative mechanism of fibrosis is by epithelial-mesenchymal transition of tubular cells to an activated myofibroblast that migrates into the interstitium.⁴⁴ Steps in this conversion include loss of cell-cell adhesion, loss of

E-cadherin, acquisition of α -smooth muscle actin, actin reorganization, tubular basement membrane disruption, cell migration, and profibrotic molecules. TGF- β may play an important role in the pathogenesis of fibrosis and epithelial-mesenchymal transition (see Fig. 96.11).

The current criteria for chronic active AMR are histologic evidence of chronic injury (in the absence of other possible causes), immunopathologic evidence of antibody action (i.e., C4d staining), and evidence of circulating antibody reactive to the donor. Chronic AMR appears to arise through a series of stages.³⁶ The first common event is alloantibody production (stage I), followed by antibody interaction with alloantigens, resulting in the deposition of C4d in the peritubular capillaries and possibly glomeruli (stage II), followed by pathologic changes (stage III) and finally graft dysfunction (stage IV). Whereas the factors promoting progression from stage I to stage IV are not currently understood, the hypothesized stages provide a useful organizing structure for ongoing clinical trials to intervene in the earlier stages (I or II).

TRANSPLANTATION TOLERANCE

Transplantation tolerance is a state characterized by the absence of a destructive immune response in the recipient toward a well-functioning donor allograft, with a fully intact immune system and no exogenous immunosuppression.⁴⁵ Like self-tolerance, transplantation tolerance is achieved through control of T-cell reactivity by both central and peripheral mechanisms. Central tolerance involves thymic deletion mechanisms that eliminate T cells with reactivity against self antigens (or donor antigens in the case of transplantation tolerance) and positive selection of T cells without such reactivity. In experimental transplant models, central tolerance is achieved by elimination of the preexisting mature T-cell population by irradiation or cytotoxic agents, followed by infusion of donor hematopoietic progenitor cells. Reconstituted donor antigen “re-educates” the thymus to delete developing T cells with antidonor reactivity, leading to a state of chimerism, in which both donor and recipient cells coexist. Translating this approach to the clinical setting, however, requires a functional thymus, which may not be present in the adult human. Peripheral tolerance mechanisms include deletion, anergy, and regulation. With self-tolerance, these mechanisms serve to prevent deleterious autoimmune responses from T cells that escape central deletion. Various approaches to induce peripheral transplant tolerance are currently under investigation, including costimulatory blockade, pharmacologic manipulation of DCs, and induction of donor antigen-specific Tregs. One of the most significant hurdles to the development of clinical tolerance strategies is the lack of reproducible immune monitoring assays to detect the presence or absence of tolerance, which would determine when immunosuppressive medications could be safely withdrawn. Although transplantation tolerance is not yet a clinical reality, progress in the field is being made.^{46,47}

Immunosuppressive Medications in Kidney Transplantation

Karl Womer, Hamid Rabb

Much of the success of kidney transplantation is a result of advancements in immunosuppressive medications that are used during the induction and maintenance phases and for treatment of acute rejection.¹ The term *maintenance immunosuppression* is usually used to describe drug regimens consisting historically of small molecule agents that are administered to stable kidney transplant recipients, particularly after the first year. Increasingly, community nephrologists and primary care physicians are becoming involved in the care of stable kidney transplant recipients during the maintenance phase. In contrast, biologic agents that are used as induction protocols before the maintenance stage or for the treatment of early or late acute rejection episodes are commonly managed by transplant surgeons and nephrologists in inpatient settings. This chapter discusses the immunosuppressive agents that either are approved for prevention of rejection in renal transplantation or are commonly used as such by most transplant centers, with specific emphasis on their biologic mechanisms of action, pharmacokinetics, and side effect profile. These agents are divided into small molecule drugs and biologic agents for the purposes of this discussion.

SMALL MOLECULE DRUGS

Corticosteroids

Corticosteroids have been a cornerstone of transplant immunosuppression for the past 50 years, both as maintenance immunosuppression and for treatment of acute rejection.

Mechanism of Action

Corticosteroids suppress production of numerous cytokines and vasoactive substances, including interleukin (IL)-1, tumor necrosis factor α (TNF- α), IL-2, major histocompatibility complex class II, chemokines, prostaglandins (by inhibition of phospholipase A₂), and proteases. Corticosteroids also cause neutrophilia (often with a left shift), but neutrophil chemotaxis and adhesion are inhibited. They also affect nonhematopoietic cells.

Corticosteroids act as agonists of glucocorticoid receptors but at higher doses have receptor-independent effects. Corticosteroid receptors (CRs) belong to a family of ligand-regulated transcription factors called nuclear receptors. CRs are normally present in the cytoplasm in an inactive complex with heat shock proteins (HSP90, HSP70, and HSP56). The binding of corticosteroids to the CRs dissociates HSP from the CR and forms the active corticosteroid-CR complex, which migrates to the nucleus and dimerizes on palindromic DNA sequences in many genes,

called the corticosteroid response element. The binding of CR in the promoter region of the target genes can lead to either induction or suppression of gene transcripts (e.g., of cytokines). CRs also exert effects by interacting directly with other transcription factors independent of DNA binding.

A key way by which corticosteroids regulate immune responses is by regulation of the transcription factors activator protein 1 (AP-1) and nuclear factor κ B (NF- κ B). Normally, NF- κ B is present as an inactive complex with inhibitor of nuclear factor κ B (I κ B), but it can be released by I κ B kinase. Corticosteroids stimulate I κ B, which then competes with the I κ B:NF- κ B complex for degradation by the I κ B kinase. Corticosteroids also stimulate lipocortin, which inhibits phospholipase A₂, thereby inhibiting the production of leukotrienes and prostaglandins. The total immunosuppressive effect of corticosteroids is complex, reflecting effects on cytokines, adhesion molecules, apoptosis, and activation of inflammatory cells.

Pharmacokinetics

The major corticosteroids used are oral prednisone (or prednisolone) and intravenous methylprednisolone. The oral agents have good oral bioavailability (60% to 100%) and have short half-lives (60 to 180 minutes) but long biologic half-lives (18 to 36 hours). Corticosteroids are eliminated by hepatic conjugation and are excreted by the kidneys as inactive metabolites. Coadministration of inducers of enzymes that metabolize corticosteroids (e.g., phenytoin, rifampin) decreases their half-life, whereas concomitant use of P-450 3A4 inhibitors (e.g., ketoconazole) has the opposite effect. As corticosteroid levels are not routinely monitored, dosage adjustment during concurrent therapy with these medications becomes problematic. For treatment of acute rejection, pulse doses of 250 to 1000 mg of methylprednisolone are typically used, with no evidence that the higher dosage is more efficacious.

Side Effects

Side effects of corticosteroid therapy are common and associated with significant morbidity, particularly cataracts, osteoporosis, and avascular necrosis of the femoral heads (Fig. 97.1). Other side effects include hypertension, hyperglycemia, hyperlipidemia, cushingoid features, psychiatric disturbances, sleep disorders, peptic ulcer disease, pancreatitis, colonic perforation, increased appetite with weight gain, growth retardation, and myopathy. Infection risk is also increased and is excessive if high-dose pulse therapy is prolonged. Interestingly, corticosteroids are not associated with increased incidence of malignant disease.

Common Side Effects of Small Molecule Immunosuppressive Medications							
	Cyclosporine	Tacrolimus	Mycophenolate	Azathioprine	Corticosteroids	mTOR Inhibitors	Leflunomide
Renal	Nephrotoxicity, type IV RTA, HTN, diuretic resistance, hyperkalemia, hypomagnesemia, hypophosphatemia	Nephrotoxicity, type IV RTA, HTN, diuretic resistance, hyperkalemia, hypomagnesemia, hypophosphatemia			HTN, hypokalemia, diuretic resistance	Synergistic nephrotoxicity with CNIs, delayed recovery from ATN, proteinuria, hypokalemia, HTN	
Gastrointestinal		Diarrhea, abdominal pain	Diarrhea, nausea and vomiting, gastritis, esophagitis, oral and colonic ulcers	Nausea and vomiting, hepatotoxicity, pancreatitis	Peptic ulcers, gastritis, esophagitis, diarrhea, colonic perforation	Diarrhea	Nausea, diarrhea, hepatitis
Hematologic	Thrombotic microangiopathy	Thrombotic microangiopathy	Anemia, leukopenia, thrombocytopenia	Anemia, leukopenia, thrombocytopenia	Leukocytosis, polycythemia	Thrombotic microangiopathy, anemia, thrombocytopenia	Anemia, leukopenia
Metabolic	Hyperlipidemia, hyperuricemia, gout, glucose intolerance	New onset diabetes			Hyperlipidemia, hyperuricemia, hyperglycemia, osteoporosis, vascular necrosis, increased appetite and weight gain	Hyperlipidemia	
Cosmetic	Gingival hyperplasia, coarsened facial features	Alopecia			Hirsutism, acne, cushingoid facies, buffalo hump	Impaired wound healing, oral ulcers	Alopecia
Neuromuscular	Encephalopathy, insomnia, myopathy, tremors	Encephalopathy, insomnia, myopathy, tremors			Psychosis, insomnia, myopathy	Reflex sympathetic dystrophy	
Other	Edema	Myocardial hypertrophy	Viral infections, pulmonary edema in elderly, progressive multifocal leukoencephalopathy		Cataracts	Lymphocele, interstitial pneumonitis, rash, edema	Rash

Figure 97.1 Common side effects of small molecule immunosuppressive medications. ATN, acute tubular necrosis; CNIs, calcineurin inhibitors; HTN, hypertension; mTOR, mammalian target of rapamycin; RTA, renal tubular acidosis.

Although corticosteroids are generally considered safe in pregnancy, orofacial clefts and fetal adrenal suppression have been reported.

Calcineurin Inhibitors

Calcineurin inhibitors (CNIs), including cyclosporine and tacrolimus, are fungus-derived small molecules that are the mainstays of current maintenance immunosuppressive regimens. Considerable variability exists in their pharmacokinetics, interactions, and side effect profiles, which raises the question of which agent to use in the individual patient. Cyclosporine is a cyclic, lipophilic peptide endecapeptide with several *N*-methylated amino acids, which may explain its resistance to inactivation in the gastrointestinal tract. Tacrolimus is a macrolide lactone antibiotic. Both drugs are highly soluble in lipids and other organic solvents.

Mechanism of Action

Both CNIs exert their effect by binding to cytoplasmic proteins called immunophilins (Fig. 97.2). Cyclosporine binds to

cyclophilin, and tacrolimus binds to FK-binding protein 12 (FKBP12).² Such binding enhances the immunophilin's affinity to and subsequent inhibition of calcineurin, which is a calmodulin-activated serine phosphatase important for dephosphorylation of inactive nuclear factor of activated T cells (NF-AT). Nuclear translocation of dephosphorylated (active) NF-AT, in association with other transcription factors, initiates downstream events leading to T-cell activation (see section on T-cell activation in Chapter 96). The tacrolimus:FKBP12 active complex inhibits calcineurin with greater molar potency than the corresponding cyclosporine complex. Cyclosporine and tacrolimus can interfere with activation of calcineurin on substrates other than NF-AT, which likely explains many of the side effects of calcineurin inhibition. Treatment with CNIs also causes upregulation of the cytokine transforming growth factor β (TGF- β), which has significant immunosuppressive properties but also promotes the deposition of matrix proteins and tissue fibrosis. Finally, these two agents can suppress the immune response by calcineurin-independent pathways as well. This mechanism generally involves blockade of intracellular signaling pathways specific for T cells.

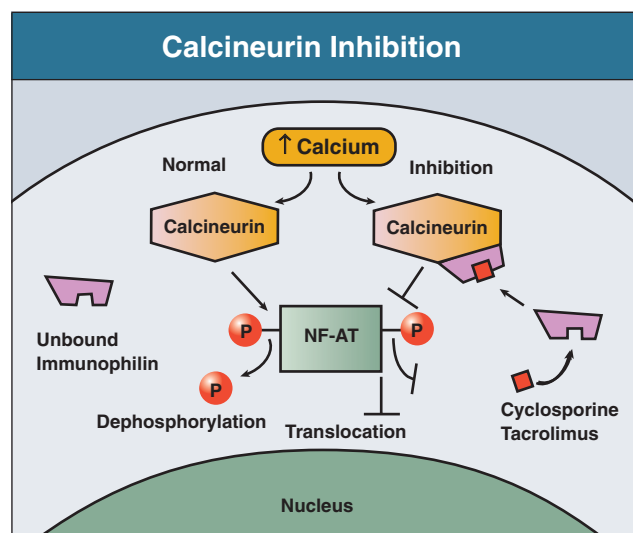

Figure 97.2 Calcineurin inhibition. During normal T-cell activation, calcium release activates calcineurin's phosphatase activity, causing dephosphorylation of the transcription factor nuclear factor of activated T cells (NF-AT) and subsequent translocation to the nucleus. Cyclosporine and tacrolimus form a complex with immunophilins (cyclophilin or FK-binding protein 12, respectively), which bind calcineurin and sterically inhibit the phosphatase activity, preventing dephosphorylation and nuclear translocation of NF-AT.

Figure 97.3 Drug levels during the course of a dosing interval. The drug concentration is lowest just before the dose is taken (C_0), then rises to a peak concentration at a certain time after the dose (C_{max}). The area under the concentration-time curve (AUC) describes total drug exposure during the entire dosing interval.

The ability of these agents to interfere with two distinct mechanisms of T-cell activation contributes to their highly specific immunosuppressive properties.

Pharmacokinetics, Monitoring, and Drug Interactions

After a dose of CNIs, there is an initial absorptive phase, during which blood concentrations reach a peak level (C_{max}).³ Typically, C_{max} occurs during the first 2 to 3 hours after the dose and corresponds to the time of maximum calcineurin inhibition. Drug levels then fall as a result of metabolism (also known as elimination phase) until they are at the lowest, or trough, level (C_0) immediately before the next dose. The total drug exposure throughout the period from one dose until the next is the area under the concentration-time curve (AUC; Fig. 97.3). For both CNIs, most of the interpatient and inpatient variability occurs in the absorption rather than in the elimination phase.

The oil-based formulation of cyclosporine requires solubilization in bile and is plagued by highly variable and unpredictable bioavailability (up to 60% AUC), which is influenced by age, ethnicity, variability of gastric milieu (bile flow, concomitant ingestion of certain foods and medications), and comorbidities such as diabetes and cystic fibrosis. The microemulsion preparation of cyclosporine (modified) has enhanced bioavailability and less dependence on bile secretion, with 70% to 135% higher blood concentrations. In blood, cyclosporine resides primarily in erythrocytes (60% to 70%) and leukocytes (9%), with some binding to lipoproteins and, to lesser extent, other plasma proteins. Cyclosporine is metabolized primarily by CYP3A4, a member of the cytochrome P-450 superfamily. Metabolism occurs mostly in the liver, although other organs, including the kidneys and gut mucosa, contain this enzyme. Interindividual differences in CYP3A4 activity and the large number of exogenous and endogenous substances capable of altering its function and expression explain the wide variation in clearance rates. One factor is the multidrug resistance 1 gene product, P-glycoprotein, which is variably expressed in the intestine and reduces the

absorption of several xenobiotics, including CNIs, by transport out of intestinal epithelial cells. The average half-life of cyclosporine is about 19 hours, with excretion primarily in bile. Generic formulations of cyclosporine modified exist, although they may not have identical pharmacokinetics and therefore may not be readily interchangeable.

The absorption of tacrolimus, like that of cyclosporine, is highly variable; bioavailability ranges from 5% to 67%. Absorption is not bile dependent but does depend on gastrointestinal transit time and is affected by the presence or absence of food as well as the lipid content of food. Clearance appears to be faster in the pediatric population, requiring administration of higher or more frequent doses. Ethnic differences exist as well, with African Americans requiring higher doses than Caucasians to achieve equivalent therapeutic levels. These differences may in part be due to expression of alternative subtypes of CYP3A (e.g., CYP3A5). In blood, tacrolimus distributes primarily to erythrocytes, with whole-blood concentrations 10 to 30 times higher than in plasma. In contrast to cyclosporine, no lipoprotein binding occurs. Tacrolimus has 20- to 30-fold higher potency than cyclosporine on a molecular weight basis. Similar to cyclosporine, metabolism occurs through the CYP3A4 system, with pharmacokinetics also affected by intestinal P-glycoprotein. Both CNIs are generally administered twice daily.

Because of their narrow therapeutic index, the variability of concentrations between patients after a dose, and the potential for drug interactions, monitoring of CNIs is required to ensure both safety and adequacy. Both cyclosporine and tacrolimus bind to cells and to plasma components (primarily lipoproteins for cyclosporine and albumin for tacrolimus) in the blood and therefore must be assayed in the whole blood. Four assays are currently used to monitor levels of CNIs in the blood: high-performance liquid chromatography (HPLC), monoclonal radioimmunoassay (RIA), monoclonal and polyclonal fluorescent polarization immunoassays, and the specific enzyme-multiplied immunoassay. Cyclosporine trough levels measured by HPLC

Drugs and Other Substances that Interact with Calcineurin Inhibitors

Figure 97.4 Drugs and other substances that interact with calcineurin inhibitors.

or RIA are comparable, as both techniques measure levels of the parent compound only. However, these concentrations are one-third lower compared with concentrations measured by techniques that detect the parent compound plus its metabolites. See Chapter 100 for standard dosing and target blood levels.

Given the complementary influence of both CYP3A4 and P-glycoprotein on their pharmacokinetic profiles, it is assumed that CNI-drug interactions are similar. Interestingly, drugs that competitively inhibit CYP3A4 activity, such as ketoconazole, usually also inhibit P-glycoprotein, thereby increasing the bioavailability of CNIs and potential for toxicity. In contrast, drugs like phenobarbital that increase CYP3A4 levels tend to upregulate P-glycoprotein, decreasing overall bioavailability. In this case, the likelihood of rejection increases. Despite similar drug interactions, the age and ethnic differences in pharmacokinetics between the two CNIs are likely to influence the degree and importance of such interactions. See Figure 97.4 for common interactions.

Side Effects

Cyclosporine and tacrolimus have similarities and differences in their toxicity profiles (see Fig. 97.1). Both can cause nephrotoxicity, hyperkalemia, hypomagnesemia and hypophosphatemia (secondary to urinary loss), renal tubular acidosis (type 4), hypertension, diabetes, and neurotoxicity. Certain side effects, such as gingival hyperplasia, hirsutism, hypertension, hyperuricemia, and hyperlipidemia, are more common with cyclosporine, whereas tremor and glucose intolerance are more common with tacrolimus. Cyclosporine may also be associated with coarsening of facial features, especially in children, and bone pain responsive to calcium channel blockers. Tacrolimus, especially in combination with mycophenolate mofetil, has been suspected of inducing more BK virus nephropathy.

The most common and vexing problem with CNIs is nephrotoxicity, with the importance evident from cardiac and liver transplant recipients, in whom large doses of CNIs are associated with progression to end-stage renal disease. Both reversible hemodynamic and irreversible structural components underlie the nephrotoxicity of CNIs. Reversible vasoconstriction is caused by direct vascular effects but is also due to activation of the renin-angiotensin system (RAS), endothelin, thromboxane, and the sympathetic nervous system. Over time, chronic renal injury occurs, which is notable for afferent arterial hyalinosis and tubulointerstitial fibrosis. It is presumed that these lesions are the result of prolonged renal vasoconstriction with ischemia. Experimentally, chronic cyclosporine nephropathy is exacerbated by the presence of sodium restriction and volume depletion, which stimulates the RAS, and can be ameliorated by angiotensin-converting enzyme inhibitors or angiotensin receptor blockers. Cyclosporine toxicity and to a lesser extent tacrolimus toxicity are potentiated in combination with sirolimus and everolimus. Finally, CNIs in high doses can cause thrombotic microangiopathy, probably by direct endothelial cell injury and dysfunction.

Mycophenolate

Mycophenolate mofetil (MMF) and enteric-coated mycophenolate sodium (EC-MPS) are important components of immunosuppressive regimens that are associated with some of the most successful outcomes in kidney transplantation.⁴ Because of its well-documented efficacy and acceptable side effect profile, MMF has become by far the most frequently used antiproliferative agent.

Mechanism of Action

The immunosuppressive effects of both these agents are likely to be mediated through the active metabolite mycophenolic acid (MPA). MMF is a morpholinoethyl ester of MPA, a potent reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH), isoform 2. EC-MPS is a salt that combines an acid-MPA with a base-sodium. The enteric coating delays MPS release so that the MPA is absorbed in the small intestine rather than in the stomach. MPA noncompetitively inhibits IMPDH, which is the rate-limiting enzyme in the *de novo* synthesis of guanosine monophosphate (GMP). Inhibition of IMPDH creates a relative deficiency of GMP and a relative excess of adenosine monophosphate (AMP). GMP and AMP levels act as a control on *de novo* purine biosynthesis; therefore, MPA, by inhibiting IMPDH, creates a block in *de novo* purine synthesis that selectively interferes with proliferative responses of T and B cells. Some other cell types, including gastrointestinal epithelial cells, use the *de novo* pathway. Thus, MPA may act directly to inhibit replication of gastrointestinal epithelial cells, leading to disruption of fluid absorption and diarrhea. However, most other cell types, including neurons, depend primarily on the alternative pathway for DNA synthesis and cell division and thus are relatively spared from toxicity.

Pharmacokinetics

MMF, being a prodrug of MPA, is absorbed rapidly and completely from the gastrointestinal tract and undergoes extensive presystemic de-esterification to become MPA, the active moiety. Food intake can delay the rate of MMF absorption but does not affect the extent. However, coadministration of antacids or cholestyramine decreases absorption by approximately 20% and 40%, respectively. EC-MPS has shown bioavailability equivalent

to that of MMF. MPA undergoes enterohepatic circulation, and its plasma concentration shows a secondary peak at 6 to 12 hours after intravenous or oral dosing. The mean contribution of enterohepatic circulation to the overall AUC of MPA is 37% (range, 10% to 61%). The majority of MPA is metabolized in the liver (and possibly other sites, including intestine and kidney) through a phase II glucuronidation process. The major metabolite of MPA is the pharmacologically inactive 7- β -glucuronide metabolite (MPAG), although two other metabolites, MPA-acyl-glucuronide (AcMPAG) and MPA-phenyl-glucoside (glucoside-MPA), are isolated from the plasma of renal transplant patients. AcMPAG has shown *in vitro* pharmacologic activity (inhibition of IMPDH) as well as proinflammatory effects and potentially is responsible for the gastrointestinal toxicity of MPA.

The glucuronide metabolites are excreted into the bile, a process that is mediated by the multidrug resistance-related protein 2 (MRPR2), then undergo de-glucuronidation back to MPA by enzymes that are produced by colonic bacteria. Blockade of MRPR2 by an inhibitor, such as cyclosporine but not tacrolimus, decreases the biliary excretion of MPAG and increases plasma MPAG levels. This eventually leads to lower plasma levels of MPA because the glucuronide metabolites no longer can be reabsorbed as MPA by enterohepatic cycling. Thus, cyclosporine-treated patients have higher exposure to MPA than tacrolimus-treated patients do, and it is possible that tacrolimus results in greater intestinal exposure to the metabolites of MPA because of greater enterohepatic circulation.⁵ The ultimate elimination pathway for the glucuronide metabolites is through the kidney, and more than 95% of an administered dose eventually is found in the urine as glucuronide metabolites.

For the most part, MMF and EC-MPS have been used exclusively in a fixed-dose regimen. However, studies have established a strong association of MPA AUC and its pharmacologic effects, specifically prevention of acute rejection. Furthermore, considerable interindividual variability is found in MPA AUC and trough concentrations in patients who receive a fixed dose of MMF. These data lend support to recent efforts to evaluate the role of therapeutic drug monitoring in increasing the therapeutic potential of MMF and EC-MPS.

Side Effects

MMF and EC-MPS have similar side effect profiles, including gastrointestinal toxicity, bone marrow suppression, and increased infections, especially those of viral etiology (see Fig. 97.1). Gastrointestinal disturbances include oral ulcerations, esophagitis, gastritis, nausea and vomiting, diarrhea, and colonic ulcers. Diarrhea and leukopenia frequently necessitate dose reduction, which can precipitate rejection. As the metabolites of MPA appear to play a major role in the gastrointestinal disturbances associated with MMF, there is little rationale for enteric coating of the prodrug to reduce these symptoms. In fact, randomized controlled trials have found no significant difference in gastrointestinal adverse events between MMF and EC-MPS.^{6,7} MMF is not routinely used during pregnancy because of its teratogenicity in experimental animal models and clinical reports of major fetal malformations.

Azathioprine

The use of azathioprine has decreased dramatically in kidney transplantation with the introduction of MMF. Azathioprine is metabolized in the liver to 6-mercaptopurine and further converted to the active metabolite thio-inosinic acid by hypoxanthine-

guanine phosphoribosyltransferase. Because allopurinol (a xanthine oxidase inhibitor) will increase the levels of thio-inosinic acid, doses of azathioprine must be reduced by two thirds in patients taking allopurinol. More often, MMF is substituted for azathioprine.

Azathioprine suppresses the proliferation of activated T and B cells and reduces the number of circulating monocytes by arresting the cell cycle of promyelocytes in the bone marrow. The antiproliferative effect is mediated by the metabolites of azathioprine, including 6-mercaptopurine, 6-thiouric acid, 6-methylmercaptopurine, and 6-thioguanine. These compounds are incorporated into replicating DNA and halt replication. They also block the *de novo* pathway of purine synthesis by formation of thio-inosinic acid; this effect confers specificity of action on lymphocytes that lack a salvage pathway for purine synthesis.

The major side effect of azathioprine is bone marrow suppression, leading to leukopenia, thrombocytopenia, and anemia (see Fig. 97.1). The mean cell volume is commonly increased in patients taking azathioprine, and red cell aplasia can occasionally occur. The hematologic side effects are dose related and usually reversible on dose reduction or temporary discontinuation of the drug. Other common side effects are increased risk of malignant disease (especially of skin cancers), hepatotoxicity, pancreatitis, and hair loss. Azathioprine is generally considered safe in pregnancy, although some fetal immunosuppression may occur.

mTOR Inhibitors

The mTOR inhibitors are proliferation signal inhibitors with potent immunosuppressive activity. Sirolimus, also called rapamycin, was the first agent used in transplantation and is a macrolide product of a soil fungus found in Easter Island.⁸ Everolimus is a rapamycin analogue with similar mechanism of action, immunosuppressive properties, and side effect profile. Although initially used in regimens with the intent of minimizing exposure to CNIs, the mTOR inhibitors have been associated with their own set of toxicities that have prevented their widespread use.

Mechanism of Action

Sirolimus has structural similarity to tacrolimus and binds the immunophilin FKBP12. The affinity of sirolimus for FKBP12 is higher than that of everolimus. mTOR inhibitors do not inhibit calcineurin or the calcium-dependent activation of cytokine genes but instead inhibit cytokine receptor-mediated signal transduction and cell proliferation and block lymphocyte responses to cytokines and growth factors. The sirolimus:FKBP12 or everolimus:FKBP12 complex binds with high affinity a kinase enzyme called mammalian target of rapamycin or mTOR, which is a serine-threonine kinase of the phosphatidylinositol 3-kinase pathway that acts during costimulatory and cytokine-driven pathways. mTOR inhibits an inhibitor (4E-BP1) and activates a ribosomal enzyme (p70 S6 kinase), both of which are important for translation of the mRNAs for certain proteins needed for progression from the G₁ phase to the S phase of DNA synthesis. mTOR has been identified as the principal controller of cell growth and proliferation. The sirolimus:FKBP12 complex inhibits mTOR-mediated signal transduction pathways by blocking postreceptor immune responses to costimulatory signal 2 during G₀ to G₁ transition and to cytokine signaling during G₁ progression. It also inhibits IL-2- and IL-4-dependent proliferation of T and B cells, leading to suppression of new ribosomal protein synthesis and arrest of the G₁-S phase of the cell cycle. Prolifera-

tion of nonimmune cells, such as fibroblasts, endothelial cells, hepatocytes, and smooth muscle cells, is also impaired by inhibition of the growth factor–mediated responses (e.g., basic fibroblast growth factor, platelet-derived growth factor, vascular endothelial cell growth factor, and TGF- β). In addition, it has been shown that mTOR contributes to several protein synthesis pathways that could be involved in oncogenesis.

Pharmacokinetics

The oral bioavailability of sirolimus is poor (10% to 16%), with significant interindividual and intraindividual variability. Peak concentrations occur approximately 1 to 2 hours after an oral dose, and sirolimus distributes extensively into tissues, including blood cells. The oral bioavailability of everolimus is higher than that of sirolimus. High-fat meals increase sirolimus levels while decreasing everolimus levels. Because sirolimus has a relatively long half-life (approximately 62 hours), it is reasonable to wait 1 week (approximately three half-lives to achieve steady state) before monitoring sirolimus blood levels after initiation or dose adjustment. Sirolimus is metabolized by the P-450 3A4 isoenzyme and P-glycoprotein system and thus has interactions similar to those described for the CNIs (see Fig. 97.4). When sirolimus or everolimus is administered simultaneously with cyclosporine, C_{\max} and AUC for both the compounds are increased. Thus, it is recommended that cyclosporine and mTOR inhibitors be administered 4 hours apart. Cyclosporine clearance may be reduced during concurrent therapy.

Side Effects

The mTOR inhibitors have a wide variety of toxicities (see Fig. 97.1). The most common adverse effects associated with sirolimus are dose-dependent hyperlipidemia (particularly hypertriglyceridemia), thrombocytopenia, and leukopenia. Other adverse effects include anemia (especially in combination with MMF), hypokalemia, impaired wound healing and dehiscence, formation of lymphoceles, rashes, oral ulcers, reduced testosterone levels, pneumonitis, and diarrhea. Although not inherently nephrotoxic, the mTOR inhibitors result in renal graft damage through several mechanisms. When it is used in combination with full-dose cyclosporine (and probably also tacrolimus), sirolimus potentiates CNI-induced toxicity, perhaps by increasing TGF- β expression. In patients with renal insufficiency, sirolimus is associated with marked yet potentially reversible proteinuria and worsening of established proteinuria. Sirolimus can also cause delayed recovery from acute tubular necrosis. Finally, cases of thrombotic microangiopathy have been reported, and there is concern that higher doses of sirolimus may inhibit endothelial cell growth. Sirolimus-based regimens have been associated with a reduced incidence of post-transplantation malignant neoplasms. Some physicians regard sirolimus as the preferred immunosuppressive agent in transplant patients who develop malignant neoplasms. Sirolimus is not routinely used during pregnancy because of its teratogenicity in experimental animal models, although successful pregnancies have been reported.

Dihydro-orotate Dehydrogenase Inhibitors

Leflunomide and its derivative, FK778, are pyrimidine synthesis inhibitors with immunosuppressive as well as antiproliferative effects. These agents inhibit dihydro-orotate dehydrogenase, which is a key rate-limiting enzyme in *de novo* pyrimidine synthesis. Unlike other cell types, activated lymphocytes expand their pyrimidine pool by nearly eightfold during proliferation,

whereas purine pools increase only twofold. Thus, inhibition of dihydro-orotate dehydrogenase prevents lymphocytes from accumulating sufficient pyrimidines to support DNA synthesis.

Leflunomide tablets are 80% bioavailable. After oral administration, leflunomide is metabolized to teriflunomide (previously A77 1726), which is responsible for essentially all of the activity *in vivo* and is monitored during therapy. Metabolism occurs in the liver, with excretion in the urine and bile. Because of its very long half-life (approximately 2 weeks), a loading dose of 100 mg for 3 to 5 days is generally used to reach steady-state levels quickly. Side effects include gastrointestinal adverse events, alopecia, bone marrow suppression, severe hepatitis, interstitial lung disease, and life-threatening skin reactions. Leflunomide use is not safe during pregnancy, and unless female leflunomide users receive cholestyramine therapy to eliminate the drug from the body, pregnancy must be avoided for 2 years after discontinuation. Although it is not approved by the Food and Drug Administration (FDA) for use in kidney transplantation, leflunomide has recently been assigned orphan drug status for the prevention of rejection in solid organ transplantation, largely on the basis of modest antiviral activity *in vitro* against BK virus and cytomegalovirus. However, the efficacy and safety of leflunomide have not been completely assessed in well-controlled and adequate studies. Furthermore, the manufacturers of FK778 discontinued development owing to a lack of benefit over current options with regard to prevention of rejection and treatment of BK virus nephropathy.

BIOLOGIC AGENTS

Biologic agents in the form of polyclonal antibodies and monoclonal antibodies (mAbs) are frequently used in kidney transplantation either as induction therapy or for the treatment of rejection. Polyclonal antibodies are derived from horses or rabbits; historically, mAbs have been murine in origin. However, because foreign proteins can elicit an immune response, there has been an attempt to replace murine monoclonal products with humanized or chimeric mAbs (Fig. 97.5). Humanized antibodies are produced by merging the DNA that encodes the antigen-binding portion of a monoclonal mouse antibody with human antibody–producing DNA. Mouse hybridomas are then used to express this DNA to produce hybrid antibodies that are not as immunogenic as the murine variety. Chimeric antibodies use the same strategy but for the entire variable region and thus are more immunogenic than humanized antibodies. Polyclonal antibodies and mAbs can be divided further into two groups: depleting agents and immune modulators.

Polyclonal Antilymphocyte Sera

Polyclonal antilymphocyte agents are produced by immunizing animals with human thymus-derived lymphoid cells. Although rabbit antithymocyte globulin (ATG) is currently the preferred preparation, equine preparations have historically been used. Most regimens involve daily intravenous administration of ATG for 5 to 7 days either as induction therapy or for treatment of corticosteroid-resistant rejection. ATG contains antibodies that react against a variety of targets, including red blood cells, neutrophils, dendritic cells, and platelets. ATG binds to multiple epitopes on the surface of T cells and induces a rapid lymphocytopenia by several mechanisms, including complement-dependent cytotoxicity, cell-dependent phagocytosis, and apoptosis. ATG is a potent immunosuppressive, and T- and B-lymphocyte

Figure 97.5 Chimeric and humanized antibodies. Chimeric antibodies consist of human constant (C) regions and mouse variable (V) regions. A chimeric antibody therefore retains the antigen binding site of the mouse antibody but fewer amino acid sequences foreign to the human immune system than a standard mouse antibody. Humanized monoclonal antibodies retain only the minimum necessary parts of the mouse antibody for antigen binding, the complementarity-determining region (CDR, highlighted in red), and therefore are even less immunogenic in the human host.

counts can remain depressed up to 24 hours after administration. The lack of specificity coupled with marked immunosuppression increases the risk of infection and malignant neoplasms. As polyclonal agents are xenogeneic proteins, they may elicit a number of side effects, including fever and chills. The initial lysis and activation of T cells that follow ATG administration may generate significant first-dose effects, with release of TNF- α , interferon- γ (IFN- γ), and other cytokines. Less commonly, ATG can induce a serum sickness-like syndrome and rarely acute respiratory distress syndrome (ARDS).

Murine Monoclonal Anti-CD3 Antibody

OKT3 is a murine IgG2a mAb targeting the ϵ chain of the CD3:T-cell receptor complex and was first approved for the treatment of rejection. Soon after OKT3 administration, T cells disappear from circulation as a result of opsonization and subsequent removal from circulation by mononuclear cells in the liver and spleen. Initially, OKT3 can activate T cells and result in release of several cytokines, including IL-2, IFN- γ , IL-6, and TNF- α . These cytokines cause a syndrome referred to as the cytokine release syndrome, which consists of fever, chills, headache, gastrointestinal complaints, and, less commonly, ARDS, aseptic meningitis, and encephalopathy. The availability of other agents and the severity of side effects associated with the cytokine release syndrome have resulted in a marked reduction in the use of OKT3. Furthermore, OKT3 is immunogenic in humans,

and approximately 50% of patients will make antibodies to it after a course of treatment, decreasing the efficacy of subsequent courses. Although several humanized anti-CD3 mAbs (huOKT3g1, HuM291) have been generated, they have not been developed for use in renal transplantation.

Humanized Monoclonal Anti-CD52 Antibody

Alemtuzumab is a humanized IgG1 mAb directed against CD52, a glycoprotein present on circulating T and B cells, monocytes-macrophages, NK cells, and granulocytes. Although it is currently approved only for the treatment of B-cell chronic lymphocytic leukemia, alemtuzumab has been used as an induction agent in renal transplantation, given its powerful depletion properties and favorable cost profile compared with other induction agents. Treatment results in a rapid and effective depletion of peripheral and central lymphoid cells that may take months to return to pretransplantation levels. Side effects of alemtuzumab include first-dose reactions, neutropenia, anemia, and, rarely, pancytopenia and autoimmunity (e.g., hemolytic anemia, thrombocytopenia, and hyperthyroidism). The risks of immunodeficiency complications such as infection and malignant neoplasia with alemtuzumab are still not clear, and further controlled trials are necessary to establish dosing, safety, and efficacy.

Monoclonal Anti-CD25 Antibody

The α subunit of the IL-2R (CD25) is upregulated on activated T cells and leads to the expression of the high-affinity IL-2R that on engagement by IL-2 triggers the activated T cell to undergo proliferation. Two mAbs, daclizumab (humanized) and basiliximab (chimeric), have been developed with specificity for CD25. These antibodies induce relatively mild immunosuppression and are used as induction agents to prevent rejection^{9,10} but not to treat established rejection. Although the exact mechanism of action is not fully understood, it is clear that significant depletion of T cells does not play a major role. Saturation of the IL-2R α subunit persists for up to 120 days after daclizumab induction and 25 to 35 days after treatment with basiliximab. Although saturation is important as a determinant of minimal blood concentrations, it is not predictive of rejection. No major side effects have been associated with anti-CD25 therapy.

B Cell-Depleting Monoclonal Anti-CD20 Antibody

Rituximab is an engineered chimeric mAb that contains murine heavy- and light-chain variable regions directed against CD20 plus a human IgG1 constant region.¹¹ The CD20 antigen, a transmembrane protein, is found on immature and mature B cells as well as on malignant B cells. CD20 mediates proliferation and differentiation of B cells. Rituximab directly inhibits B-cell proliferation and induces apoptosis and lysis by complement-dependent cytotoxicity, antibody-dependent cell cytotoxicity, and activation of tyrosine kinases as a direct effect of the antibody's binding to its CD20 ligand. Rapid and sustained depletion of circulating and tissue-based B cells occurs after intravenous administration, and recovery does not begin until approximately 6 months after completion of treatment. Although plasma cells are usually CD20 negative, many are short-lived and require replacement from CD20-positive precursors. In addition, CD20-positive B cells can act as secondary antigen-presenting cells, thereby enhancing T-cell responses. Thus, by targeting CD20 on precursor B cells, rituximab decreases the production

of activated B cells and limits their antibody production as well as antigen presentation capability.

Most adverse events are first-infusion effects, such as fevers and chills, and are generally of mild severity. Moreover, these adverse effects occur less frequently during subsequent infusions. Viral infections, including reactivation of hepatitis B virus and JC virus (progressive multifocal leukoencephalopathy), have been reported, although it is not known whether these events are specific to the agent or instead reflect the overall state of immunosuppression. Antichimeric antibodies develop in some cases, but their true incidence and therapeutic significance are uncertain.

Rituximab is currently approved by the FDA only for treatment of B-cell non-Hodgkin's lymphoma and rheumatoid arthritis. However, given the effects on B-cell depletion, this agent has been used in kidney transplantation to treat antibody-mediated rejection as well as in combination with intravenous immune globulin to reduce high-titer anti-HLA antibodies in highly sensitized patients awaiting renal transplantation.¹² Rituximab is also used as induction therapy after desensitization therapy for ABO blood group-incompatible and high-risk positive-crossmatch kidney transplantation. Finally, rituximab is often used to treat post-transplantation lymphoproliferative disease.

Intravenous Immune Globulin

Intravenous immune globulin (IVIG) products are known to have powerful immunomodulatory effects on inflammatory and autoimmune conditions. The mode of action of IVIG is not understood. In renal transplantation, the most important effect appears to be a reduction of alloantibodies through inhibition of antibody production and increased catabolism of circulating antibodies. Additional potential mechanisms include inhibition of complement-mediated injury, inhibition of inflammatory cytokine generation, and neutralization of circulating antibodies by anti-idiotypes.

Side effects related to IVIG administration include minor self-limited reactions, such as flushing, chills, headache, myalgia, and arthralgia. Rarely, anaphylactic reactions may occur. Delayed reactions include severe headache and aseptic meningitis, which respond to analgesics. More recently, severe thrombotic events have been linked to the administration of IVIG products. Of

concern to renal transplant recipients is the development of acute renal failure due to osmotic injury of the proximal tubular epithelium after administration of sucrose-containing IVIG preparations. This tubular injury is self-limited and can be minimized or avoided by use of sucrose-free preparations.

In combination with plasmapheresis, IVIG appears to offer significant benefits in the desensitization of positive-crossmatch and ABO-incompatible patients to allow successful transplantation as well as in the treatment of antibody-mediated rejection. Alone or in combination with rituximab, IVIG has been successful in the desensitization of highly sensitized wait-listed patients to increase the chances of finding a compatible donor.

Evaluation and Preoperative Management of Kidney Transplant Recipient and Donor

William R. Mulley, John Kanellis

Renal transplantation provides superior long-term outcomes compared with dialysis, in both quantity and quality of life, although the benefit gained varies between individuals.¹ The improvement in outcomes coupled with the shortage of available organs has led to an expansion of donor criteria and an increasing tendency for centers to accept marginal donor kidneys.² In this chapter, we review current recommendations for the evaluation and preoperative management of both the kidney transplant donor and recipient.

RECIPIENT EVALUATION

Many units now accept patients who were previously excluded from transplantation, such as those with human immunodeficiency virus (HIV) infection, obesity, and diabetes. This is due to the availability of newer treatment options for some conditions and a greater understanding of the impact of these conditions on patient and graft survival along with changing societal attitudes on equality of access to transplantation. Some absolute contraindications to transplantation remain (Fig. 98.1), including significant current infection or malignant disease, noncompliance or substance abuse, and any condition likely to severely limit life expectancy (<1 to 2 years).³⁻⁵

Whereas the application of guidelines for transplant suitability may be relatively straightforward for patients with a single comorbidity, it is not as simple for those with multiple medical conditions who represent a growing group of transplant recipients. Determination of suitability in such patients often requires input from specialists in a variety of medical and surgical disciplines along with allied health professionals. The final decision needs to be a joint one between clinician and patient after full and open discussion of the likely risks and benefits followed by regular reassessment of suitability while the patient awaits transplantation.

A summary of guidelines published by national and international transplantation associations³⁻⁵ is presented in Figure 98.2. Some of the important areas to consider in evaluating the transplant recipient are discussed here.

Cardiovascular Disease

Cardiovascular disease is the major cause of death in renal transplant recipients. Hence, cardiovascular evaluation is critical in the evaluation of the transplant recipient.

Coronary Heart Disease and Left Ventricular Dysfunction

Renal failure itself is a major risk factor for coronary artery disease. However, the vascular lesion, clinical features, and

response to treatment may be quite different in patients with renal failure compared with the normal population. Because of a lack of conclusive evidence, the role of pretransplantation screening and intervention for coronary artery disease is controversial, making definite recommendations difficult. However, given the high incidence of cardiac events in the peritransplantation period and its major contribution to post-transplantation mortality, we favor aggressive screening and intervention in at-risk patients while avoiding unnecessary tests and procedures in low-risk candidates. Patients may be stratified into risk groups on the basis of history and examination, resting electrocardiography, and chest radiography. Further screening is unnecessary in asymptomatic patients without risk factors because of a very low incidence of coronary events.⁶ Further investigation is recommended, however, in patients with abnormal test results or significant risk factors, such as previous ischemic events, diabetes, smoking, age older than 50 years, hypertension, dyslipidemia, prolonged renal failure (>2 years), or a family history of ischemic heart disease.³⁻⁵

Symptomatic patients should proceed directly to coronary angiography; noninvasive functional testing should be used to screen the need for angiography in asymptomatic patients.⁷ Exercise echocardiography or thallium imaging is preferred; however, pharmacologically driven testing may be necessary if exercise is not possible. Whereas a normal result does not exclude coronary artery disease, it has a negative predictive value for myocardial infarction or cardiac death in excess of 96% in patients with renal failure.⁸ If significant coronary artery disease is identified, treatment before transplantation should be instituted. Treatment consists of medical management including aggressive risk factor modification and angioplasty and stenting or coronary artery bypass grafting in patients with significant stenoses.⁷ A suggested approach is presented in Figure 98.3.

In patients with clinical or radiologic evidence of left ventricular dysfunction, transthoracic echocardiography should be performed to assess the severity and nature of the dysfunction. If it is significant, a cause should be sought and treated when possible. Whereas mild to moderate left ventricular dysfunction may improve after transplantation, severe dysfunction in a patient with a short life expectancy is considered a contraindication to transplantation unless, in rare instances, combined heart and kidney transplantation is appropriate.³⁻⁵

Cerebrovascular Disease

Patients with a history of recent transient ischemic attack or stroke are at greatest risk of recurrence early after the primary event; and because stroke after transplantation is associated with a high rate of mortality,⁹ a waiting time of 6 months is

Contraindications to Renal Transplantation	
Current Absolute Contraindications to Transplantation	Previous Contraindications to Transplantation (now acceptable under certain circumstances – see text)
<ul style="list-style-type: none"> Active Sepsis Current uncontrolled malignant disease Uncontrolled psychosis Active drug dependence Any medical condition with a severely shortened life expectancy (<1–2 years) Positive T-cell CDC cross match 	<ul style="list-style-type: none"> HIV Infection Hepatitis B and C Obesity Mood disorders Age > 60 years Previous malignant disease Blood group incompatibility

Recipient Evaluation Checklist
History and Examination Cause of renal failure and risk of recurrence Sensitization (transfusion, pregnancy, previous transplant) Past and current infections (TB, hepatitis, HIV) Immunization (especially hepatitis B) Malignancy Cardiovascular risks (smoking, hypertension, diabetes) Pulmonary, gastrointestinal disease Genitourinary tract Psychiatric, psychological history Surgical issues (weight, iliac vessels, abdomen, previous surgery)
Laboratory and Radiologic Investigations Viral serology (HIV, CMV, EBV, hepatitis B and C) Liver function tests Bone-related issues (PTH, calcium, phosphate) Chest radiograph Electrocardiogram Prostate-specific antigen (for men >50-60 years old) Mammogram or breast ultrasound (women >50 years old or with family history of breast cancer) Pap smear (sexually active women)
Immunologic Investigations ABO blood group and HLA typing Screening for HLA antibodies and autoreactive antibodies Crossmatching

Figure 98.2 Recipient evaluation. CMV, cytomegalovirus; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; PTH, parathyroid hormone; TB, tuberculosis.

recommended. Meanwhile, aggressive risk factor modification should be undertaken to limit the likelihood of further stroke. Routine screening for cerebrovascular disease is not advocated in asymptomatic patients. Recent evidence suggests a benefit in further investigation of patients with a carotid bruit and treatment with carotid endarterectomy if a significant stenosis is found.¹⁰ Evidence on the merits of screening for and treatment of asymptomatic cerebral artery aneurysms in patients with polycystic kidney disease is inconclusive, making definite recommendations difficult at this time.

Peripheral Vascular Disease

Asymptomatic patients with strong femoral and peripheral pulses generally require no further investigation. Patients with diabetes, history of claudication, or reduced pulses require vascular imaging

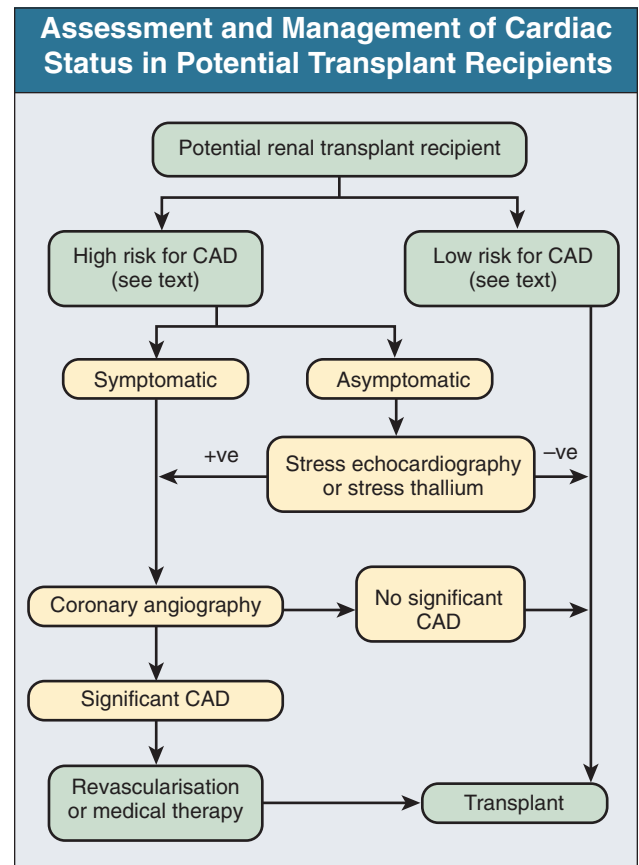

Figure 98.3 Assessment and management of cardiovascular disease in potential transplant recipients. CAD, coronary artery disease; +ve, positive; -ve, negative.

beginning with Doppler ultrasound. Significant disease involving the iliac vessels may make transplantation difficult or impossible and may worsen ischemia in the distal leg. Although it is not an absolute contraindication to transplantation, peripheral vascular disease is associated with increased mortality¹¹ and should be considered in conjunction with the patient's other comorbidities.

Cancer

Cancer is a major cause of death in renal transplant recipients. Further increases in the incidence of malignant disease are likely

with increased graft survival and acceptance of older recipients. The incidence of malignant disease is also increased in transplant recipients compared with the general population.¹² However, the effect of transplantation on different types of cancers is not uniform, nor is the effect of different immunosuppressive agents.¹³ Some cancers, such as non-melanoma skin cancers (61% to 82% at 20 years) and lymphoma, have a markedly increased incidence in transplant recipients compared with the general population; other malignant neoplasms, such as breast and prostate, are not as markedly increased.¹⁴ In patients with a previous malignant neoplasm, guidelines have been devised on the basis of the likelihood of recurrence after transplantation (Fig. 98.4). In general, the longer the cancer-free interval before transplantation, the smaller the recurrence risk. For most malignant neoplasms, a period of 2 to 5 years is recommended.³⁻⁵ There are several exceptions. A longer waiting time (≥ 5 years) is recommended for breast cancer with nodal involvement, melanoma, and colorectal cancer worse than stage B1; no waiting time is thought necessary for non-melanocytic skin cancers confined to the skin, *in situ* cancers of bladder and cervix, focal microscopic low-grade prostate cancer, and small incidentally discovered renal cell carcinomas. Given the heterogeneity of malignant neoplasms, waiting periods before transplantation need to be individualized, taking into account the patient's other comorbidities.

Although extensive screening of all potential recipients is not warranted, guidelines appropriate for the general population should be adopted in screening for breast, cervical, prostate, and colorectal cancer. Chest radiography is performed as part of the routine assessment. More comprehensive and targeted evaluation is recommended in patients with a strong family history or suggestive clinical features of malignant disease or conditions associated with an increased risk of malignant disease, such as renal imaging in patients with acquired cystic disease of the kidney for possible renal cell carcinoma.^{3,4}

Infectious Complications

All patients are screened for previous exposure to Epstein-Barr virus and cytomegalovirus (CMV) to assess the risk of infection,

Screening Tests for Occult Infection		
Routine Serology	Where Indicated, Tests for	Other Routine Investigations
Hepatitis B virus Hepatitis C virus HIV Cytomegalovirus Epstein-Barr virus	Human herpesvirus 8 HTLV <i>Strongyloides stercoralis</i> Malaria <i>Trypanosoma cruzi</i> Schistosomiasis	Urine culture Chest radiograph

Figure 98.5 Screening tests for occult infection. Routine screening tests for occult infection. HIV, human immunodeficiency virus; HTLV, human T-cell lymphotropic virus.

either primary or reactivation. This guides the appropriate use of prophylactic antiviral agents. For example, patients who are negative for CMV IgG who receive a kidney from a CMV-positive donor are at the highest risk of infection and may benefit from prolonged prophylaxis compared with the lower risk CMV-negative donor to CMV-negative recipient (see Chapter 101). Screening for other infections should be tailored to geographic location; a guide for screening is presented in Figure 98.5. Immunization against hepatitis B should be undertaken in all potential recipients. Immunization against encapsulated organisms (pneumococcus, *Haemophilus influenzae*, and meningococcus) should also be considered in patients at high risk of antibody-mediated rejection in case splenectomy is required.

Before highly active antiretroviral therapies (HAART), HIV infection was considered an absolute contraindication to transplantation because of very poor patient survival.¹⁵ In the HAART era, HIV infection is seen as a manageable chronic disease, and transplantation is offered to HIV-positive patients at many major centers. Short- to medium-term results in the small studies reported suggest excellent patient and graft survival.¹⁶ Larger studies are under way to further explore these outcomes. Patients with sustained CD4 counts above 200/ml and undetectable HIV viral loads, without an AIDS-defining illness, could be considered for transplantation at a center experienced in managing HIV infection and transplantation.

Patients with hepatitis B may be considered for renal transplantation if there is no evidence of active viral replication (hepatitis B virus [HBV] DNA or hepatitis B early [HBe] antigen positive), advanced liver disease or cirrhosis (as determined by liver biopsy), or hepatocellular carcinoma.³⁻⁵ Immunosuppression can increase HBV replication; hence, treatment before transplantation is indicated in patients with active disease, and although data to support prophylactic antiviral therapy after transplantation are scarce, it is commonly practiced while immunosuppression is at its highest (initial 12 to 24 months). Early reports suggest that mortality may be increased in HBV-positive patients after transplantation compared with HBV-negative recipients.¹⁷ The significance of these findings is unclear in the current era with more effective treatment options and if only patients with inactive disease are transplanted. Frank disclosure of possible risks involved is recommended.³⁻⁵

Patients with hepatitis C should be assessed by measurement of hepatitis C viral (HCV) load and a liver biopsy. Treatment should be instituted before transplantation; however, candidates who do not clear the virus may still proceed with transplantation as mortality in this group is improved compared with those remaining on dialysis.¹⁸ HCV-positive patients may in some

units, with informed consent, receive a kidney from an HCV-positive donor. Any possible increased risk may be offset by a significantly reduced waiting time. Patients with hepatitis B and C should be screened every 12 months for hepatocellular carcinoma by liver ultrasound and serum alpha-fetoprotein. Those with cirrhosis may be considered for combined kidney-liver transplantation.

The risk of tuberculosis reactivation after transplantation should be assessed by chest radiography and a tuberculin skin test. Whereas a positive test response correlates with past infection, false-negatives in uremic patients are common.¹⁹ Patients at high risk (previous tuberculosis, abnormal chest radiograph or positive skin test response, or resident in an endemic area) who have not been previously treated should receive prophylactic isoniazid after transplantation (see Chapter 101).

Previous graft loss due to polyoma (BK) viral nephropathy is not a contraindication to repeated transplantation. Limited data currently prevent specific recommendations on the benefit of waiting for serum and urine BK polymerase chain reaction test results to become negative or on the value of graft nephrectomy before repeated transplantation. Vigilant screening for recurrence is recommended.⁵

Obesity

Transplantation in obese patients (body mass index [BMI] $>30 \text{ kg/m}^2$) generally improves survival compared with matched waiting list controls, but inferior outcomes for patient and graft survival, delayed graft function and wound healing, and infective complications have been reported in obese compared with non-obese patients, particularly those with a BMI above 36 kg/m^2 .²⁰ There are several reports to the contrary, however, including a recent multivariate analysis of registry data suggesting that obesity is not associated with worse graft and patient survival when comorbidities are controlled for.²¹

However, the overweight or obese are more likely to develop new-onset diabetes after transplantation, which can adversely affect graft and patient survival. Potential transplant recipients with obesity should be advised to lose weight as a means to decrease this risk before transplantation.

Recurrent Disease

The risk of disease recurrence needs to be discussed as part of the informed consent process, particularly in certain primary renal diseases (e.g., focal segmental glomerulosclerosis). Graft loss attributed to recurrent disease has increased in recent years but still accounts for only 5% of graft loss.²² The risks and management of recurrent disease are discussed in Chapter 104.

Gastrointestinal Disease

Screening for gastrointestinal disease is not warranted in the asymptomatic patient.^{4,5} Patients with active acute or chronic pancreatitis should not undergo transplantation until they have been clear of symptoms for 12 months. Patients with active peptic ulcer disease should be treated before transplantation with proton pump inhibitors, and this should be continued to prevent ulceration after transplantation. Patients with symptomatic diverticular disease require colonoscopy and potential colonic resection in severe cases before transplantation as they are at increased risk of perforation on immunosuppressive medications.⁴ Whereas symptomatic cholecystitis should be treated

surgically before transplantation, asymptomatic cholelithiasis does not require surgery before transplantation because cholecystectomy after transplantation is required in less than 10% of these patients and results in no increased mortality or morbidity compared with pretransplantation cholecystectomy and no deleterious effects on graft function.²³

Genitourinary Disorders

Screening for genitourinary disorders before transplantation is indicated in those with a history or renal ultrasound suggestive of urinary obstruction, especially in children, in whom urologic problems are a major cause of end-stage renal disease. If obstruction is found, urologic assessment, which may include voiding cystourethrography and urodynamic studies, is indicated to determine the best course of action to limit bladder pressures after transplantation; this may involve bladder augmentation, urinary diversion, or self-catheterization.

Native nephrectomy before transplantation should be considered for recurrent or persistent renal sepsis, particularly in the setting of nephrolithiasis. Very large polycystic kidneys may need to be removed to accommodate the transplant kidney. Whether previous grafts should be removed before repeated transplantation is controversial. Nephrectomy of a failed graft is commonly performed on withdrawal of immunosuppression in patients with early graft failure (<12 months)²⁴ to alleviate symptoms such as pain over the graft, fever, and weight loss.²⁵ Other indications include graft sepsis and to allow room for the new graft. However, unless there is a convincing reason to remove the graft, it is generally left *in situ*. In these circumstances, the patient may need to stay on a minimal amount of immunosuppression (e.g., prednisolone, 5 mg/day) to minimize graft tenderness and inflammation. Graft nephrectomy may be associated with an increased risk of HLA sensitization,²⁴ perhaps relating to loss of antigen-dependent tolerogenic mechanisms²⁶; this, however, is not a universal finding. Another advantage of leaving the previous transplant *in situ* is preservation of any residual renal function and urine output.

Pulmonary Disease

Initial assessment by physical examination and chest radiography is indicated for all potential recipients; further testing, such as pulmonary function tests or computed tomographic scanning, is performed if it is clinically indicated. Recent guidelines suggest that patients with a short life expectancy associated with pulmonary disease, such as cor pulmonale, uncontrolled asthma, and severe obstructive lung disease ($\text{FEV}_1 <25\%$ of predicted or $\text{Po}_2 <60 \text{ mm Hg}$ on room air), or those needing home oxygen be excluded from transplantation.⁵ Many units require patients to cease smoking before acceptance as smokers have an increased risk of death and graft loss. Cessation of smoking demonstrates positive lifestyle behavior and good compliance, suggesting these factors will be optimized in the post-transplantation period.

Psychosocial Issues

Psychosocial issues can have a major impact on transplant outcomes. Patients should be evaluated by a social worker or other health professional experienced in judging capacity to consent and assessing likely compliance with a transplant medication regimen. Compliance with the post-transplantation treatment regimen is vital to minimize premature graft loss. Predicting

Figure 98.6 Re-evaluation of suitability for transplantation.

compliance can be challenging and may be based on pretransplantation compliance, such as adherence to dialysis management regimens. If compliance is unlikely, as judged by medical, psychiatric, psychological, and social work assessment, transplantation should not proceed.^{3–5}

Cognitive impairment is not an absolute contraindication to transplantation as long as appropriate supports and proxy arrangements are in place. Patients with psychiatric illnesses including depression, bipolar affective disorder, and psychosis require assessment by a psychiatrist to determine transplant suitability and to devise a management plan to cope with possible consequences of immunosuppressive medications such as corticosteroids.^{3–5} Drug and alcohol addiction should be addressed with rehabilitation and demonstrated abstinence before listing for transplantation.

Re-evaluation of Patients on the Waiting List

Patients may wait several years on the transplant list before receiving an opportunity to be transplanted. It is vital that when their opportunity comes, they are still suitable. A targeted reassessment of waiting list patients therefore should be conducted at regular intervals (Fig. 98.6). General measures, such as sun avoidance and cancer screening (e.g., prostate, breast, and cervical), should be continued on a regular basis as indicated. Reassessment of cardiac status is advocated on the basis of risk. Diabetic and other high-risk patients should be reassessed every 1 to 2 years.⁷ The value of reassessing low-risk patients is more questionable, but given that renal failure is a strong risk factor for cardiac disease, repeated stress testing by exercise or pharmacologically driven echocardiography or thallium scanning at least every 3 years seems appropriate. Patients with preexisting medical conditions (e.g., HIV infection and viral hepatitis) require regular specialist reviews, with any issues arising brought to the attention of the transplant team. Surgical reassessment may be needed in patients with peripheral vascular disease, with weight gain, or if a complication such as peritonitis occurs while awaiting transplantation. Patients should be temporarily removed from the waiting list if they develop a serious infection or other illness until it is resolved.

DONOR EVALUATION

Donor kidneys can be obtained from both deceased and living donors.

Deceased Donors

Classification of the Deceased Donor

Deceased donors can be classified as either heart-beating donors with loss of brainstem function (donation after brain death or DBD) or non-heart-beating donors (donation after cardiac death or DCD). In recent years, the proportion of DCD donors is increasing in many countries as a result of policies aiming to maximize the opportunities for donation.

DBD donors can be further divided into standard criteria donors and extended criteria donors. Whereas the definition of extended criteria donor varies, in the United States it refers to heart-beating donors older than 60 years or 50 to 59 years old with two or three of the following criteria: a history of hypertension; elevated serum creatinine at donation (>1.5 mg/dl or 130 μ mol/l); death from a cerebrovascular accident. In some jurisdictions, the term *marginal donor* is loosely used to describe donors who are less than optimal for some reason. This is usually due to the presence of significant underlying disease (hypertension, diabetes, vascular disease, renal impairment) or advanced age (>65 years).

Donation after cardiac death can occur by several mechanisms. The Maastricht classification separates these types of donors into controlled and uncontrolled categories (Fig. 98.7).²⁷ Controlled donors are those who suffer cardiac arrest after withdrawal of support or after brain death. Uncontrolled donors are those who are deceased on arrival to the hospital or who have a failed cardiopulmonary resuscitation. From a practical point of view, a system that uses controlled donors is easier to implement than one using uncontrolled donors. This is largely related to factors surrounding ethical considerations and the consent process involving relatives of the donor.

The survival of kidneys from extended criteria donors and from some categories of DCD donors is generally inferior to that of kidneys retrieved from standard criteria donors.^{28,29} Many matching schemes attempt to allocate these less ideal grafts to recipients who are predicted to have a lower than average overall survival, but practice varies considerably between countries with regard to these issues.

Evaluation of the Deceased Donor

In most circumstances, organ donor coordinators screen potential deceased donors after referral from hospital intensive care units or emergency departments. Patient records are assessed and relatives are interviewed about important aspects of the

Classification of Donation after Cardiac Death Donors
As per Maastricht classification (Kootstra, 2007) (also known as non-heart-beating donors)
Uncontrolled
Category I: Dead on arrival to hospital Cause of death is usually obvious (e.g. severe head injury) and no resuscitation is given
Category II: Unsuccessful resuscitation The subject is brought to the emergency department while being resuscitated, but this is not effective. Alternatively, arrest occurs in hospital and subject is unable to be resuscitated
Controlled
Category III: Awaiting cardiac arrest Severe brain injury without brain death. Subjects are usually ventilator dependent. Arrest occurs once support is withdrawn
Category IV: Cardiac arrest while brain dead Subject suffers cardiac arrest after being declared brain dead. Alternatively, this occurs during brain death testing and the subject is not or cannot be successfully resuscitated
Category V (see Ch. 99)

Figure 98.7 Classification of donation after cardiac death (DCD) donors.²⁷

clinical history. The assessment focuses on general health (including history of infections and cancer), social history (especially drug use and sexual history), and laboratory evidence of renal impairment or other diseases (Fig. 98.8). Patients with sepsis, acute hepatitis, or HIV infection are excluded from donation, as are those with a history of malignant disease. Non-melanomatous skin cancers do not lead to exclusion, nor do primary brain tumors unless they are of a high grade or the donor has received chemotherapy or had a craniotomy or cerebral shunt inserted.³⁰ In some centers, donors potentially carrying hepatitis B or hepatitis C virus are accepted only for those positive for these viruses. The risk of an unknown donor malignant neoplasm is approximately 1.3%; however, the risk of transmitting a donor malignant neoplasm is lower at approximately 0.2%.³¹

Evaluation of renal function is determined by history, urinalysis, and serum creatinine concentration. In some cases, a biopsy (often performed at retrieval) may provide useful information, particularly with extended criteria donors.³² Serum creatinine concentration at admission should be in the near-normal range (estimated glomerular filtration rate [GFR] >60 ml/min), but a temporary decline in renal function is acceptable if the function is expected to recover. Proteinuria (>0.5 g/24 h) indicates structural renal damage and is a valid reason for nonacceptance.

The use of kidneys from very small donors varies between centers. Donors younger than 5 or 6 years are generally associated with high risk of failure, especially from vascular thrombosis.³³ For this reason, some centers occasionally transplant two kidneys—transplanted en bloc, using the aorta and inferior vena cava as conduits.³⁴

Deceased Donor Management Before Transplantation

In the brain-dead donor, maintenance of an adequate blood pressure and oxygenation are important to avoid warm ischemic renal

injury. The use of pressor agents, volume resuscitation, and other conditioning strategies is complex and has been the subject of several guideline documents (see the Intensive Care Society website, www.ics.ac.uk). In this category of donor, the kidneys are generally not subject to significant warm ischemia at the time of organ retrieval unless the donor suffers prolonged hemodynamic compromise.

In donation after cardiac death, once death is certified and deemed irreversible, either rapid surgical exposure of the great vessels with cooling of the organs followed by prompt retrieval is required or, alternatively, the kidneys are cooled *in situ* by

insertion of perfusion catheters through the femoral vessels. Surgical retrieval can then take place after a period of delay to variably allow one or more of the following: family counseling, donor assessment, or relocation from one hospital area to another (e.g., from the intensive care unit or emergency department to the operating theater). Donation after cardiac death is inevitably associated with warm ischemic renal injury. This is responsible for the higher rate of delayed graft function that is seen in this group. The need for dialysis support after transplantation is on average 50% but varies from 30% to 90%, depending on the category of donor.²⁷

Living Donors

Live kidney donation is currently justifiable in most countries on the basis of the demand for deceased donor organs—which far outweighs the supply—as well as the apparent very low level of risk to the majority of healthy donors.³⁵ Added to this are the detrimental effects for the recipient of waiting on dialysis and the excellent, generally superior results obtained through use of live donors.

Living donors may be related, unrelated, altruistic, or part of a donor exchange or list-exchange program. In many countries with well-established transplant programs, half or more of all transplants are now performed with living donors. In Japan, Brazil, and the Middle East, more than 80% of transplants use living donors. The superior success of transplantation from live donors compared with that from deceased donors has supported the development of live donor paired exchange and live donor–deceased donor exchange.³⁶ In the first instance, live donors who are incompatible with their intended recipients are exchanged between recipients. In the other instance, the donor donates to the wait list in exchange for the intended recipient's receiving priority on the list.³⁷

In some countries, either a state-organized or free-market system results in the purchase of live donor kidneys; this is a highly controversial area and under active international policy development.³⁸ The Declaration of Istanbul on organ trafficking and transplant tourism and the World Health Organization both condemn the exploitation of living donors who are thought to be vulnerable (illiterate, impoverished, undocumented immigrants, prisoners, and political or economic refugees).³⁹

In recent times, many units have extended their selection of donors to include subjects who are mildly hypertensive, overweight, or hyperlipidemic or have other abnormalities (such as isolated hematuria or previous stone disease).⁴⁰ Whereas donation appears to be safe in the short to medium term for most of these subjects, adequate studies have not been performed to assess the longer term medical or psychological effects.

Mortality and Morbidity

Mortality related to living donation is a catastrophic and unexpected event. Registry data and institutional surveys suggest the perioperative risk of donor death is approximately 3 in 10,000.⁴¹ Donor mortality and major complications appear equivalent with laparoscopic and open donor nephrectomy. In open surgery, the risks are related to perioperative complications, including pulmonary emboli, pneumonia, and ischemic events. With laparoscopic surgery, complications are largely due to catastrophic intraoperative events or postoperative bleeding related to securing of the vascular pedicle.^{41,42}

In the longer term, survival of donors appears to be similar to that of control subjects in the general population (Fig. 98.9).

Figure 98.9 Survival of living kidney donors. The survival of living related donors is similar to the expected survival derived from the general population. Error bars at 5-year intervals indicate 95% confidence intervals for the probability of survival among kidney donors. (Modified with permission from reference 35.)

Numerous series report early operative complications after laparoscopic and open donor nephrectomy with rates of between 3% and 38%.⁴¹ These reports variably include events such as bleeding, wound infection, urinary retention, pneumonia, asymptomatic and symptomatic pneumothorax, ileus, and need for transfusion, among other things. This enormous variability relates to both definition of complication and accuracy of reporting.

Case series report that physical and psychological function in living donors is higher than the community norm. Physical issues reported by donors after donation frequently include a temporary decrease from baseline in energy; some note a longer time to full recovery than anticipated and incision pain that lasts longer than expected. Psychological factors usually include an improved relationship with the recipient, an improved self-image, and frequently a positive effect on the donor's life. Longer term psychological morbidity appears minimal; however, some series have reported an association with anxiety, depression, or other psychological issues in a small proportion of the subjects.^{43,44} Even though most donors have a positive experience, a small number for a variety of reasons do regret the decision to donate (0% to 5%). Psychological evaluation before donation is therefore extremely important, as is the need to provide support and counseling after donation. This issue is particularly important when the transplant does not go as well as anticipated.

Evaluation of the Live Donor

Several groups have developed guidelines for the evaluation of the living donor, including the Amsterdam forum⁴⁵ and consensus guidelines published by several U.S. transplant centers.⁴⁶ An outline of the usual donor evaluation is shown in Figures 98.10 and 98.11. It includes a thorough history and examination, blood and urine screening tests, chest radiography, electrocardiography, age- and family history–appropriate cardiac stress test, and radiographic assessment of the kidneys and vessels. An assessment of the anatomy may be achieved by computed tomographic

angiography or magnetic resonance angiography, depending on the particular center. Formal renal arteriography, although informative, is no longer necessary given the anatomic detail obtainable noninvasively with modern radiologic techniques.

Assessment of Renal Function

Most centers use a GFR of 80 ml/min per 1.73 m² as the lower limit for donors. It is accepted that this is an overgeneralization, potentially representing too low a limit for the younger donor (e.g., <40 years) and too high a limit for the older donor (e.g., >60 to 65 years). For this reason, an alternative approach is to consider the age-specific GFR and to accept donors only if they fall within the average for this figure. This method has been recommended by the British Transplantation Society (guidelines available at www.bts.org.uk) and is presented in Figure 98.12. An alternative approach uses the life expectancy of the donor.⁴⁷ By use of these calculations, a 30-year-old donor would require a GFR of 123 ml/min per 1.73 m²; the level for a 70-year-old would be approximately 68 ml/min per 1.73 m².

Hypertension in the Live Donor

Donation may be acceptable for some hypertensive individuals if blood pressure is well controlled, GFR is as expected for

donation and age, and there are no features of end-organ involvement from hypertension.^{45,46} The evaluation for hypertension should include blood pressure measurements on three separate occasions. Borderline elevated levels should be further evaluated with ambulatory blood pressure monitoring. If elevated blood pressure is detected and the prospective donor is still under consideration, echocardiography (looking for left ventricular hypertrophy), ophthalmologic evaluation (looking for hypertensive retinal changes), and assessment for microalbuminuria (suggesting hypertensive renal damage) should be undertaken. The prospective donor should be excluded if any of these features are present.

Obesity and Abnormal Glucose Tolerance in the Live Donor

Although many centers accept obese living donors, several issues need to be addressed. This includes the impact of obesity on perioperative complications, future renal function, and cardio-

Figure 98.12 Acceptable glomerular filtration rate (GFR) in living donors by age. Diagram explaining the minimum acceptable age-associated GFR in living donor candidates. The solid orange line shows the variation with age of mean GFR. The outer dashed lines show the +2 and -2 population standard deviation (SD) limits. GFR is constant up to the age of 40 years and then declines at the rate of 9 ml/min per 1.73 m² per decade. The reference plot is based on an analysis of data for 428 live renal transplant donors who had ⁵¹Cr-ETDA GFR measurements. The solid blue line shows the safety limit of 86 ml/min per 1.73 m² for young adults, declining to 50 ml/min per 1.73 m² at age 80 years. For transplant donors with preoperative GFR values above the solid blue line, the GFR of the remaining kidney will still be above 37.5 ml/min per 1.73 m² at age 80 years. (Modified with permission from the revised British Transplantation Society/Renal Association U.K. guidelines for living donor kidney transplantation available at www.bts.org.uk/.)

vascular health. In one study, obese (BMI >30 kg/m²) subjects had an increased rate of proteinuria and renal impairment 10 to 20 years after nephrectomy.⁴⁸ Obese individuals may therefore be more prone to development of renal disease after donation, but this issue has not been carefully studied.

Future risk of diabetes is another important consideration. As well as close assessment of those who are overweight, prospective donors with an abnormal fasting glucose concentration, a history of gestational diabetes, or a first-degree relative with diabetes should be evaluated with an oral glucose tolerance test. An abnormal glucose tolerance test result is a contraindication to donation. Subjects often lose weight and otherwise change their lifestyle (exercise, diet), leading to an improvement in their results and eventual acceptance as donors. It is important that these lifestyle and risk modifications be sustained after donation occurs.

Renal Abnormalities in the Live Donor

As well as factors identified in the history (e.g., previous calculi, urinary tract infections, prostatic disease), a variety of previously unidentified renal abnormalities can be encountered in prospective donors during their assessment. These include microscopic hematuria, evidence of reflux disease, renovascular abnormalities, and renal masses and cysts.

Isolated hematuria in a prospective donor necessitates consideration of thin basement membrane nephropathy, Alport's syndrome (carrier status in women may have minor or moderate abnormalities), and IgA nephropathy as well as urinary tract infection, malignant disease, and nephrolithiasis. Microscopic hematuria is a relatively common problem, with persistent

microscopic hematuria evident in approximately 3% of the general population.⁴⁹ Among the possible disorders, IgA nephropathy is generally a contraindication to live donation, whereas thin basement membrane disease may not necessarily be so.⁵⁰ The implications of isolated mesangial IgA without other manifestations of nephropathy require further study, and donation should be decided in the context of family history, absolute renal function, presence of interstitial disease, and age. If persistent isolated asymptomatic hematuria is detected during live donor evaluation, a workup should include cystoscopy and urinary cytology if the hematuria is not clearly glomerular in origin. A renal biopsy should be considered when there is glomerular hematuria or the possibility of familial disease (e.g., Alport's syndrome, IgA nephropathy) because this aids the decision-making process by clarifying the prospective donor's future risk of progressive renal disease.⁵¹

Those with a history of bilateral or recurrent stones and those with systemic conditions associated with recurrent stone disease should not donate. An asymptomatic potential donor with a current single stone is suitable if the donor does not have a high risk of recurrence, if the stone is smaller than 1.5 cm, and especially if the stone is potentially removable during transplantation.⁴⁵ The evaluation of an asymptomatic donor with a single prior episode of nephrolithiasis should include evaluation of serum calcium, creatinine, albumin, and parathyroid hormone levels; spot urine for cystine; urinalysis and urine culture; spiral computed tomographic scan; chemical analysis of the stone, if available; and 24-hour urine measurement of oxalate, urate, and creatinine.

Atherosclerotic renal vascular disease is a relative contraindication to living donation. If it is discovered, the donor should be normotensive, have normal renal function, and have only unilateral disease.⁵² Careful evaluation for coronary disease and peripheral vascular disease should be undertaken, given the significant association of renovascular disease with atherosclerosis elsewhere. Fibromuscular dysplasia is found in 2% to 4% of prospective donors. Donors with severe and diffuse disease should not be accepted for donation. The age of the prospective donor should also be considered, with the outcome in donors older than 50 years more predictable and benign than in younger donors.⁵³

Malignant Disease

A past history of certain malignant neoplasms is considered a contraindication to live kidney donation. These include melanoma, testicular cancer, renal cell carcinoma, bronchial and breast cancer, choriocarcinoma, hematologic malignant neoplasm, and multiple myeloma.⁴⁵ A history of malignant disease may be acceptable for donation if prior treatment of the malignant neoplasm does not decrease renal reserve or place the donor at increased risk of renal disease and prior treatment of malignant disease does not increase the operative risk of nephrectomy. A history of malignant disease may be acceptable if the specific cancer is curable and transmission of the cancer can reasonably be excluded; consultation with an oncologist may be required. Consent to receive a renal transplant must include a discussion with the donor and the recipient that risk of transmission of malignant disease cannot be completely excluded.

Cardiovascular and Pulmonary Disease

In prospective donors, the cardiac assessment should be based on the history, risk factors, examination, and electrocardiographic findings. An exercise or pharmacologic stress test and echocardiography may be warranted in certain circumstances.

Individuals with myocardial dysfunction or coronary ischemia are at increased anesthetic risk and should generally not donate. Pulmonary contraindications to donation include chronic lung diseases that significantly increase the anesthetic risk. If it is indicated by history and examination, pulmonary function testing, echocardiography, or sleep studies should be performed. In all cases, donors should cease smoking for at least 8 to 12 weeks before surgery to minimize the risk of postoperative pneumonia.

COMPATIBILITY AND IMMUNOLOGIC CONSIDERATIONS

Blood Group Compatibility

Traditionally, transplantation across incompatible blood groups has been avoided owing to the risk of hyperacute rejection mediated by preformed anti-A or anti-B antibodies to the carbohydrate blood group antigens, expressed by endothelial cells as well as by red blood cells. In recent years, ABO-incompatible transplantation has become more widespread, largely on the basis of excellent outcomes described initially by Japanese units.⁵⁴ “Desensitizing” the recipient can avert hyperacute rejection. This involves removal of blood group antibodies by plasma exchange or immunoadsorption to achieve target titers. Preemptive splenectomy or rituximab administration (anti-CD20 monoclonal antibody) is often also employed; however, the need for these measures is not clear.⁵⁵ Rejection is predicted by high initial antibody titers and high rebound titers early after transplantation.⁵⁶ Further plasma exchange or immunoadsorption is generally required after transplantation for at least 2 weeks to reduce the chances of rejection. With use of this protocol, patient and graft survival appears to be equivalent to that of blood group-compatible transplantation for the short to medium term (up to 9 years).⁵⁴ Longer term results are awaited. A comprehensive overview and summary of current approaches relating to antibody-incompatible transplants is available at the British Transplantation Society website, www.bts.org.uk.

HLA Compatibility

“Tissue typing” of recipient and donor determines their human leukocyte antigen (HLA) match. HLA antigens are coded on chromosome 6, with half (one haplotype) inherited from each parent. The major histocompatibility class I HLA-A and HLA-B and class II HLA-DR antigens are routinely determined as rejection responses are thought to most commonly stem from mismatches at these alleles. There is an increasing awareness of the importance of immune responses to other HLA antigens, and many centers now look for the presence of antibodies to HLA-C, HLA-DQ, and HLA-DP. A six-antigen (HLA-A, HLA-B, and HLA-DR) match confers a graft survival advantage compared with 0 antigen matches for both cadaveric and live donor transplantation of 10% at 10 years.^{57,58} In addition to determination of the HLA compatibility, crossmatching and screening for anti-HLA antibodies are performed to assess the risk of rejection.

Assessing HLA Sensitization

The principle of screening for antibodies against HLA antigens using panel reactivity is shown in Figure 98.13. IgG antibodies against class I (HLA-A and HLA-B) antigens are highly associated with acute rejection and are a contraindication to transplantation. IgM antibodies against HLA antigens may also predict

Figure 98.13 Principle of screening for anti-HLA antibodies. The patient's serum is tested with a panel of cells of known HLA types. The most common HLA antigens are represented in such panels. In this example, the A3 antigen is the only antigen present in the two lysed cell populations and absent from the nonlysed samples. Therefore, the patient's serum contains anti-HLA A3 antibodies.

rejection if they are present in current but not past sera; however, they may also be falsely positive. Prior treatment of sera with dithiothreitol can remove IgM antibodies and aid in the interpretation of the test (Fig. 98.14). Autoantibodies (such as may occur in lupus) may also give false-positive results and can be determined by prior absorption with autologous lymphocytes.

Sensitization to HLA antigens generally occurs through blood transfusion, pregnancy, or prior transplantation. Presence in the recipient of antibodies to donor-specific HLA antigens can result in hyperacute rejection. Crossmatching of donor lymphocytes with recipient serum allows screening for this possibility. Terasaki and coworkers pioneered the complement-dependent cytotoxicity (CDC) crossmatch.⁵⁹ This assay determines the presence of antibodies thought to be of clinical significance by mixing donor T or B lymphocytes with recipient serum in the presence of complement. The sensitivity of the assay can be augmented by the addition of anti-human globulin. Presence of a positive T-cell CDC crossmatch to the donor is highly predictive of hyperacute rejection,^{59,60} whereas a B-cell CDC crossmatch is more subject to false-positives but should prompt a search for donor-specific antibodies.⁶¹ A positive T-cell crossmatch is an absolute contraindication to transplantation.

The flow crossmatch is more sensitive than the CDC in detecting antibody capable of binding to donor T or B lymphocytes. Binding of antibody from donor serum is detected by flow cytometry after probing with a fluorescein-labeled anti-immunoglobulin antibody. The predictive value of a positive flow crossmatch for rejection is less than that of a CDC crossmatch because of its increased sensitivity, and it does not assess the ability of the antibody to fix complement. In most centers, it is not routinely performed before cadaveric donor transplants, but it is commonly performed in a live donor transplant workup. A positive flow crossmatch (with a negative CDC crossmatch) is not an absolute contraindication to proceeding; however, it may lead the team to alter the immunosuppressive regimen (e.g., desensitization protocol) to decrease the risk or severity of antibody-mediated rejection.

Interpretation of the Crossmatch Test					
Antibody to MHC Class	Crossmatch (normal procedure)		Crossmatch (dithiothreitol)		Risk of Antibody-Mediated Graft Damage
	T Cells	B Cells	T Cells	B Cells	
IgG against class I	+	+	+	+	Yes
IgM against class I	+	+	–	–	Yes, IgM class I antibodies may be harmless if present in old sera only but not in the current serum
IgG against class II	–	+	–	+	Yes
IgM against class II	–	+	–	–	Unknown
IgM autoantibodies	+	+	–	–	No

Figure 98.14 Interpretation of the crossmatch test.

Determination of the presence of anti-HLA antibodies in the recipient's serum is increasingly used as a means of predicting rejection. This virtual crossmatch compares the specificity of the antibodies identified with the prospective donor's HLA typing. Donor-specific anti-HLA antibodies are correlated with worse graft survival even in the setting of a negative crossmatch.⁶² As well as through panel reactive antibody testing, antibodies can be detected by enzyme-linked immunosorbent assay or more sensitive antigen-coated bead technology (Luminex). Beads are coated with a single HLA antigen and are mixed with recipient serum and probed with a fluorescein-labeled anti-immunoglobulin antibody. Beads that bind antibody are therefore identified by fluorescence. The decision on whether to proceed with transplantation in the context of this information is complex. Current recommendations for detection and characterization of clinically relevant antibodies in solid organ transplantation are summarized by the British Society of Histocompatibility and British Transplantation Society and are available at www.bts.org.uk.

Kidney Transplantation Surgery

Adam D. Barlow, Nicholas R. Brook, Michael L. Nicholson

SOURCES OF KIDNEYS FOR TRANSPLANTATION

The usual and most frequent source of kidneys for transplantation has been donation before cardiac death (DBD), formerly known as the heart-beating cadaveric donor. The increasing worldwide discrepancy between the availability of and need for renal allografts¹ has led to the increasing use of alternative sources of organs, including donation after cardiac death (DCD) cadaveric donors (previously known as non-heart-beating donors) and live donors. The evaluation and selection of donors are discussed in Chapter 98. Here we discuss surgical aspects of retrieval and transplantation of kidneys.

DONATION BEFORE CARDIAC DEATH DONORS

The potential DBD donor is maintained by artificial ventilation in a critical care setting until death has been diagnosed by brainstem death criteria,² the consent of the next of kin for donation has been given, and the necessary legal and institutional approvals have been obtained.

In the operating room, the initial step is cannulation of the aorta and inferior vena cava while the heart is still beating. This allows perfusion of the organs with cold preservative solution immediately before cardiac arrest, minimizing warm ischemia. The priorities of the organ retrieval team are influenced by the range of organs being donated. Heart, lung, and liver retrieval take priority over kidney retrieval, which may significantly lengthen the ischemic time. The kidneys are removed *en bloc*, and the artery is typically retrieved with a cuff of aorta (Carrel patch), with the maximum achievable length of renal vein and 10 to 15 cm of ureter. The length of the right renal vein may be maximized by including a portion of inferior vena cava in continuity. Care is taken to avoid damage to polar and other accessory arteries, especially the lower pole artery, which may supply the ureter; stripping of adventitial tissue from the ureter must also be avoided, which may also compromise its blood supply.

The kidneys are flushed with ice-cold preservation fluid until the effluent is clear and then are stored for transport in crushed ice or on a perfusion machine (see [Renal Preservation](#)).

DONATION AFTER CARDIAC DEATH DONORS

Before consensus on the definition of brainstem death, DCD donors were the main source of transplant organs. These donors were intensive care unit based and had suffered head injuries or cerebrovascular accidents deemed irrecoverable, but organ retrieval could proceed only after cardiorespiratory death. This changed with the introduction of brainstem death legislation, but

the use of DCD kidneys has recently increased again in response to the shortage of suitable organs for transplantation. An international consensus has defined categories of DCD donors³ to facilitate legal and ethical discussion and to highlight possible differences in organ viability (see Fig. 98.7). DCD kidneys suffer a period of warm ischemia (the period between cardiac death and the time that *in situ* cold perfusion is started). The duration of ischemia correlates with rates of primary nonfunction, delayed graft function, acute rejection, and allograft and patient survival. The main requirement of organ procurement from DCD donors is therefore to achieve rapid *in situ* perfusion of the kidneys to limit warm ischemia. This requires an emergency response team of surgeons and transplant coordinators, with considerable on-call and logistic commitments.

DCD donors may be either uncontrolled (Maastricht categories I and II) or controlled (Maastricht categories III to V) (Fig. 98.7). In controlled donors, cardiac arrest is expected, and it is therefore possible to reduce the warm ischemia time to only a few minutes, as the surgical retrieval team will be on standby. Unexpected donor cardiac arrest may result in prolonged warm ischemia times. The duration of reversible warm ischemia time that the human kidney can sustain is unknown, but DCD kidneys with warm ischemia exceeding 60 minutes are considered by many to be of marginal suitability.

Donation After Cardiac Death Protocol

Centers involved with DCD donation should adhere to the Maastricht protocol,⁴ which includes the following principles:

- Approval by the local medical ethics committee.
- Diagnosis of death by physicians who are independent of the transplantation team.
- 10-minute rule (after declaration of cardiac death, the body is left untouched for a period of 10 minutes before intervention).
- Rapid *in situ* cooling by a catheter inserted into the aorta.
- Organ retrieval by standard surgical techniques.

Uncontrolled DCD Donors

After a period of unsuccessful resuscitation and confirmation of cardiac death and observation of the 10-minute rule, cardiac massage and ventilation with 100% oxygen are recommenced in an attempt to deliver oxygenated blood to the kidneys. A mechanical resuscitation device may be used. *In situ* renal cooling is effected by placing a double-balloon, triple-lumen perfusion catheter into the aorta through a femoral artery cutdown (Fig. 99.1), with instillation of preservation solution.

Figure 99.1 Technique for *in situ* perfusion of donation after cardiac death kidneys. A double-lumen, double-balloon arterial catheter is introduced through the femoral artery; the lower balloon is inflated at the aortic bifurcation and the upper balloon above the renal arteries. Ice-cold perfusion fluid is introduced and vented through the femoral vein until the effluent becomes clear.

Alternatively, the donor can be moved to an operating room as soon as death has occurred, and the aortic perfusion catheter is placed directly at laparotomy rather than through a femoral artery cutdown.

Controlled DCD Donors

Here the transplantation team awaits cardiac arrest; after confirmation of death, the 10-minute rule is observed, and then the perfusion catheter is inserted through the femoral artery. Alternatively, the patient can be taken to the operating room before cardiac death if the next of kin gives consent.

LIVE KIDNEY DONORS

In the United States in 2008, 45% of renal transplants were from live donors,⁵ compared with 25% in the United Kingdom.⁶ After a rapid increase in live donor transplantation at the beginning of this decade, rates have become more static. The superior recipient post-transplantation outcome compared with kidneys from deceased donors,⁷ the potential for preemptive transplantation before dialysis, and the ability to plan the procedure (allowing optimization of the recipient's condition) are major advantages and justify continued efforts to expand live donation. The medical evaluation of the live donor is discussed in Chapter 98 (see Figs. 98.10 and 98.11).

Preoperative Imaging

Preoperative imaging of live donors confirms the presence of two functioning kidneys, indicates disease that would preclude donation, and provides anatomic information necessary for planning of the procedure. Imaging assumes paramount importance before minimal access donor nephrectomy because of the reduced operative exposure and particular difficulties in the identification of complex renal vein tributaries. The location, size, and number of renal veins and tributaries need to be accurately described preoperatively. Angiography combined with excretion urography is now obsolete. For preoperative description of the main renal artery and vein anatomy, magnetic resonance angiography and computed tomographic angiography are comparable,⁸ but computed tomographic angiography is more sensitive and specific for complex vascular anatomy and provides excellent correlation between imaging and surgical findings (Fig. 99.2).⁹

Minimal Access Donor Nephrectomy

Live donor nephrectomy has traditionally been performed through an open incision, necessitating a prolonged period of recovery. This and the cosmetic implications of a large flank wound may discourage potential donors (Fig. 99.3). To reduce such disincentives, there has been a move toward minimally invasive donor nephrectomy, first performed as a transperitoneal laparoscopic procedure (laparoscopic donor nephrectomy [LapDN]).¹⁰ LapDN is associated with decreased severity and duration of postoperative pain, shorter inpatient stay, quicker return to work and normal activities, and improved cosmetic result compared with open donor nephrectomy (Fig. 99.4).¹¹ Furthermore, the overall societal cost of LapDN is lower, and the recipient's quality of life scores are higher.¹² The procedure is technically demanding, however, and there is potential for damage to the renal parenchyma, vessels, and ureter during dissection. It takes longer than open nephrectomy and exposes the allograft to a longer period of warm ischemia.¹¹

Nevertheless, retrospective data suggest that minimal access donor nephrectomy not only offers postoperative advantages to the donor but also increases the number of transplants performed by reducing donor disincentives; estimates range from a 25% to a 100%¹³ increase in transplantation activity. The widespread introduction of LapDN at the beginning of this decade saw an initial dramatic increase in the number of live kidney donors. However, rates have been static in both the United States and the United Kingdom during the last 5 years, suggesting that we may have seen the maximum benefits of this effect. Three minimal access approaches have been described: transperitoneal, extraperitoneal, and hand-assisted live donor nephrectomy.

Transperitoneal Laparoscopic Donor Nephrectomy

Pneumoperitoneum is established, and four laparoscopic ports are usually required (Fig. 99.5). After laparoscopic dissection, a Pfannenstiel incision is made through which the kidney is brought out within an endoscopy retrieval bag after control and division of the artery, vein, and ureter.

Hand-Assisted Laparoscopic Donor Nephrectomy

The hand-assisted technique allows tactile sense to facilitate dissection, retraction, and exposure. It is said to be easier to learn and can be safely and efficiently performed by surgeons with less laparoscopic experience. The hand-assisted device allows the

Figure 99.2 Live donor preoperative computed tomographic angiography. **A**, Three-dimensional reconstruction of arterial supply. Note the lower pole artery to the right kidney (arrow), which may supply the ureter as well as the lower pole parenchyma. **B**, Conventional image showing single artery and vein to the left kidney.

operator's nondominant hand to enter the abdomen through an airtight system.

Retroperitoneoscopic Operative Technique

The retroperitoneal approach avoids breaching the peritoneum, displays the renal anatomy in a very different manner, and may be easier for retrieval of the full length of the vessels, especially on the right side. The disadvantage is that a more limited operating space is available than with the transperitoneal or hand-assisted laparoscopic techniques.

Contraindications to Minimal Access Donor Nephrectomy

There are no absolute contraindications other than those applying to the open operation. The relative contraindications are dictated by donor factors and the experience of the surgeon. The

Figure 99.3 Flank wound from open nephrectomy.

Donor Benefits of Minimally Invasive Donor Nephrectomy

Shorter incisions
Less pain
Shorter hospital stay
Shorter recovery
Better cosmetic appearance

Figure 99.4 Donor benefits of minimally invasive donor nephrectomy.

donor must be fit for anesthesia, including the physiologic stress of pneumoperitoneum. Obesity is a relative contraindication to both open and laparoscopic surgery, and the hand-assisted approach may be better suited in such patients. Previous abdominal surgery is another relative contraindication because of the potential for adhesions. Multiplicity of renal vessels should not hinder LapDN.

Effect of Pneumoperitoneum

Transient intraoperative oliguria secondary to decreased renal blood flow is a frequent occurrence during laparoscopic procedures. Proposed mechanisms include decreased cardiac output, renal vein compression, ureteral obstruction, renal parenchymal compression, and systemic hormonal effects. Intracranial pressure increases during pneumoperitoneum, with release of vasoconstrictor agents that decrease renal blood flow. Use of a lower pressure reduces the adverse effects of pneumoperitoneum on renal perfusion. In donor nephrectomy, impaired renal blood flow may compromise early allograft function and compound the damaging effects of warm and cold ischemia and operative manipulation of the kidney. Laparoscopically derived donor kidneys have higher serum creatinine up to 1 month after transplantation compared with open surgery, but thereafter graft function is equivalent.¹⁴ The pioneers of LapDN report using high volumes of crystalloid preoperatively and intraoperatively to maintain renal perfusion in the presence of pneumoperitoneum. The authors have seen two episodes of unilateral

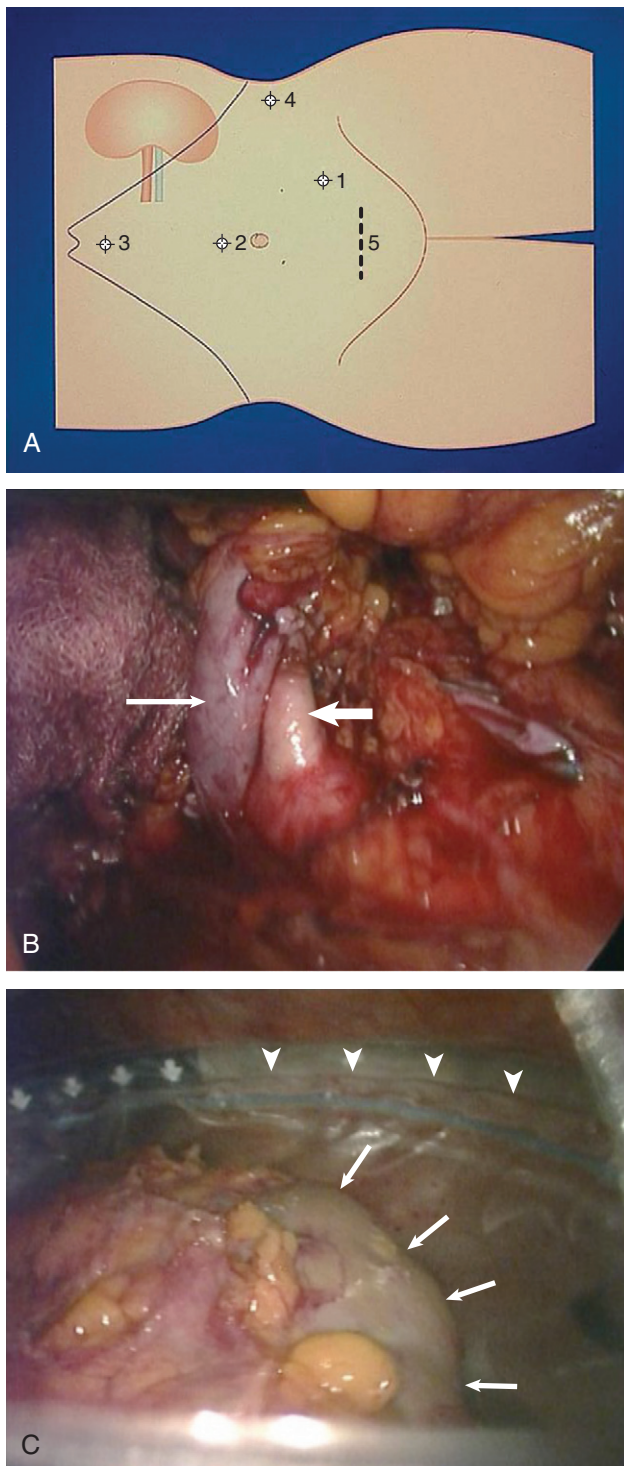

Figure 99.5 Technique for laparoscopic donor nephrectomy. **A**, Positions for four laparoscopic ports (1 to 4) and Pfannenstiel incision (5) through which the kidney is removed. **B**, Intraoperative view showing left renal artery (short arrow) and vein (long arrow) prepared for control and division. **C**, Intraoperative view showing the kidney (arrows) in the endoscopic retrieval bag (arrowheads mark edge of bag).

pulmonary edema in the dependent lung, and we now recommend volume loading of the donor with 2 liters of crystalloid the night before surgery and use of replacement fluid only during surgery. This protocol has led to no apparent detriment to graft function.

Graft Function and Acute Rejection

There is no consistent evidence that graft function differs between kidneys retrieved by open, laparoscopic, or hand-assisted donor nephrectomy. The exception is that rates of delayed graft function and acute rejection may be higher in pediatric recipients, especially the 0- to 5-year age group.

Pretransplantation ischemia could, in theory, render the donor kidney more immunogenic by inducing major histocompatibility complex class II expression. However, despite the longer warm ischemia time, acute rejection rates and severity of rejection are not higher in laparoscopic than in open live donor kidneys.

Technical Issues

Ureteral ischemia was more common in early experience of LapDN, but it can be avoided if care is taken to ensure that sufficient periureteral tissue is taken and that the dissection does not occur too close to the renal pelvis.

Multiple arteries need not be a barrier to successful use of grafts from laparoscopic donors. In open donor nephrectomy, the right kidney is retrieved in 20% to 30% of cases, whereas LapDN uses the right kidney in less than 10%,¹⁵ reflecting concern about the operative safety of the right-sided laparoscopic operation, principally the difficulties involved in obtaining an adequate length of renal vein. It has been argued that this practice has led to compromise of the principle that the better kidney should remain with the donor.

Postoperative Recovery

After uneventful open nephrectomy, the donor can expect to be discharged from the hospital in 5 or 6 days and can return to work in 8 to 12 weeks. After LapDN, the donor usually leaves the hospital in 2 to 4 days and can return to work in 4 to 6 weeks.

Choice of Donor Operative Technique

The choice of operative procedure depends on the local expertise of the surgeons. There is accumulating evidence that the laparoscopic operation removes some of the disincentives to donation, and this approach is likely to be adopted widely in the future.

RENAL PRESERVATION

Preservation of deceased donor organs is crucial to allow time for matching, sharing of organs, and preparation of the recipient. Damage from hypothermia and reperfusion must be minimized. There is little standardization of the type of preservation solution used. Marshall's hyperosmolar citrate solution and histidine-tryptophan-ketoglutarate are popular choices in Europe, but the University of Wisconsin solution is more commonly used in the United States as extended preservation times are more commonly required.

Organs can be preserved by cold storage (kept in crushed ice after flushing with preservation solution) or by machine-driven pulsatile perfusion. The proposed benefits of machine perfusion come from allowance of aerobic function through provision of oxygen and substrate and removal of metabolic end products. Although machine perfusion has been used for many years, there

is still no consensus about its superiority to cold storage or about the best perfusion parameters.

Decisions on the use of a kidney from a marginal donor can be supported by data from machine perfusion. High perfusion pressures are associated with primary nonfunction and delayed graft function.

RENAL TRANSPLANTATION PROCEDURE

The transplanted kidney is placed heterotopically in one or other iliac fossa. The inferior epigastric vessels are ligated, as is the round ligament of the uterus in female patients. On occasion, the inferior epigastric artery may be preserved and used for revascularization of small polar arteries. In male patients, the spermatic cord is mobilized and preserved. The peritoneum should not be breached but instead swept superiorly to reveal the extraperitoneal bed into which the transplanted kidney will be placed. The iliac blood vessels are then mobilized, with care taken to meticulously ligate all the associated lymphatic channels to reduce the risk of post-transplantation lymphatic leak.

Vascular Anastomosis

The renal vein is anastomosed end to side to the external iliac vein. The arterial anastomosis can be performed either end to side to the external iliac artery or end to end to the divided internal iliac artery (Fig. 99.6). The end-to-side anastomosis is technically easier and is the usual method employed in cadaveric transplantation, in which it is possible to include a Carrel aortic patch with the renal artery.

With live donor kidneys, it is not possible to include a Carrel patch, and it is preferable to anastomose the renal artery end to end to the divided internal iliac artery. If there is no Carrel patch and the internal iliac artery is not available for anastomosis because of severe atheroma, it is possible to anastomose the renal artery directly to the external iliac artery without a patch. However, the external iliac artery has a much thicker wall than the renal vessel, increasing the likelihood of technical errors, in particular, narrowing of the anastomosis.

After completion of the vascular anastomoses, the kidney must sit in such a position that the renal vessels are not kinked. The transplanted kidney can be placed laterally in the iliac fossa, or it may be placed in a subrectus pouch fashioned specifically for the purpose.¹⁶ In the latter case, the renal vessels run laterally from the kidney, and this needs to be noted in performing a post-transplantation biopsy. An operative diagram of the position of the kidney and vessels is therefore a vital component of the clinical notes.

If there are multiple renal vessels, the number of anastomoses should be minimized. This can usually be achieved by careful bench surgery before implantation. If there are two or more renal arteries, their aortic patches are joined in such a way that a single arterial anastomosis is required. If necessary, recipient iliac artery or saphenous vein is used to facilitate reconstruction. Small polar arteries will occasionally be recognized only after a kidney has been retrieved, and it is particularly important to reanastomose lower polar arteries accurately as these may provide all the ureteral blood supply. In the case of double renal veins, the most common course of action is simply to ligate the smaller vein; the larger one is usually sufficient to drain the whole kidney. If there are two equally sized veins, both may need to be anastomosed separately to the external iliac vein.

Figure 99.6 Vascular anastomosis techniques for renal transplantation. **A**, End-to-side anastomosis to the external iliac artery. **B**, End-to-end anastomosis to the divided internal iliac artery, suitable for live donor transplantation in which no aortic patch is available.

Urinary Drainage

The traditional method of ureteral anastomosis is the Politano-Leadbetter technique, involving a transvesical ureteroneocystostomy with creation of a submucosal antireflux tunnel. The end of the transplanted ureter is drawn through a submucosal tunnel from outside to inside and sutured to the bladder mucosa. Many surgeons now prefer the technically simpler extravesical ureteroneocystostomy onlay, in which the spatulated end of the ureter is anastomosed to the cystostomy and the divided muscle layer is then resutured over the ureter to create a short antireflux muscle tunnel. The onlay method has the advantage of being possible with only a short length of ureter. The shorter the ureter, the less likely it is that there will be an inadequate blood supply to the distal end, thereby reducing the risks of ischemic ureteral leaks or stenosis. A temporary double-J ureteral stent is usually placed. Stents reduce the impact of small technical errors while the ureter is leaking and reduce major urologic complications to an incidence of 1.5%.¹⁷ However, they are a potential source of urinary infection, can become encrusted or blocked by debris, and can migrate or fragment. Nevertheless, antibiotic prophylaxis is not justified as it increases the risk of infection with multiresistant organisms. Another danger is the forgotten stent that has not been removed, which should always be considered in patients with unexplained and persistent lower urinary tract symptoms after transplantation. Stents are usually removed 4 to 6 weeks after transplantation, and this can be performed without general anesthesia by use of a flexible cystoscope.

Alternative Techniques of Urinary Reconstruction

Renal transplantation is commonly performed in patients who have abnormal bladders. In many cases, it is possible to anastomose the transplanted ureter to the bladder in the hope that the bladder can be rehabilitated, if necessary, by post-transplantation intermittent self-catheterization. Nonetheless, some patients require urinary diversion with an ileal conduit. The conduit should be fashioned at least 6 weeks before transplantation, but it may have been present for many years. If so, a CT conduitogram should be performed before transplant to exclude conduit stenosis (rare) and to delineate conduit anatomy and position. The transplanted kidney is best placed in the ipsilateral iliac fossa to avoid tension in the ureter, and it may be preferable to deliberately place the transplanted kidney upside down so that the ureter runs cranially and has a more direct route to the conduit. After revascularization, the peritoneum is opened and the ureter is anastomosed to the conduit over a double-J stent. Excellent long-term results have been achieved with this technique.¹⁸

Drainage and Wound Closure

Both the transplant bed and the subcutaneous tissues are drained to prevent the accumulation of serosanguineous fluid or lymph around the transplanted kidney. The skin is best closed with a subcuticular absorbable suture and then dressed with a clear adhesive dressing so that ultrasound scanning can be performed early without disturbing the wound. Metal skin clips make ultrasound more difficult, and some units avoid using them for this reason.

Postoperative Course

The recipient is nursed in a general ward with standard precautions and no need for reverse barrier nursing. If recovery is

straightforward, the bladder catheter and wound drains are usually removed by day 5, and the recipient is fit for discharge after 7 to 10 days to be kept under close outpatient monitoring.

SURGICAL COMPLICATIONS OF RENAL TRANSPLANTATION

There is a small but significant incidence of technical complications, which can be minimized by avoiding damage to the kidneys at the time of the retrieval. Nonetheless, the presence of multiple renal vessels and donor atherosclerotic disease do increase the likelihood of technical problems in the recipient, as do recipient obesity, atherosclerosis, and previous transplantation.

The two most common clinical presentations requiring evaluation in the early postoperative period are sudden oliguria or anuria and pain or swelling over the graft. Algorithms to aid in the management of these problems can be found in Figures 99.7 and 99.8. A discussion of common surgical complications follows.

Management of Sudden Oliguria or Anuria in the Early Post-Transplant Period

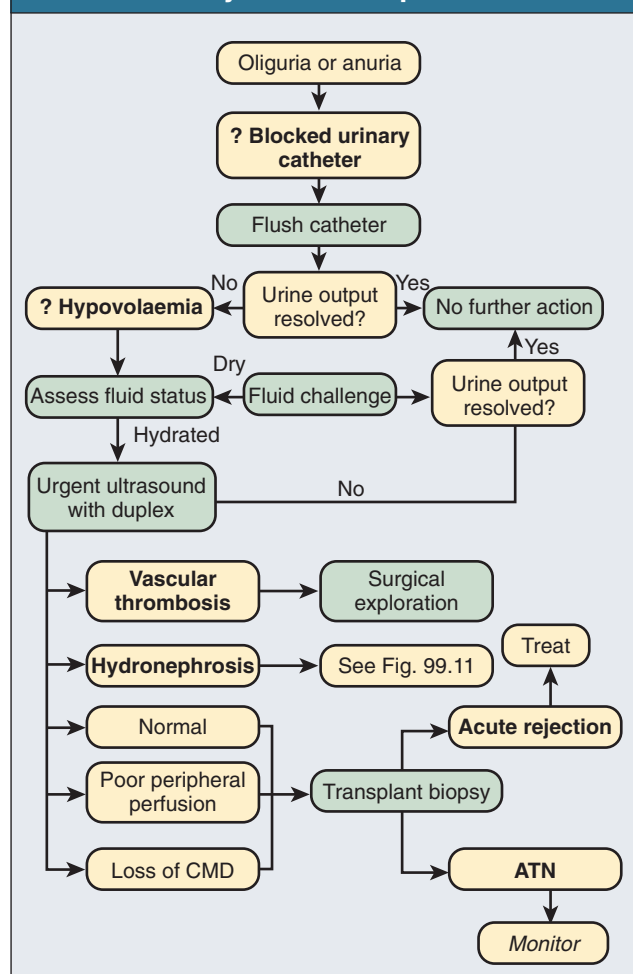

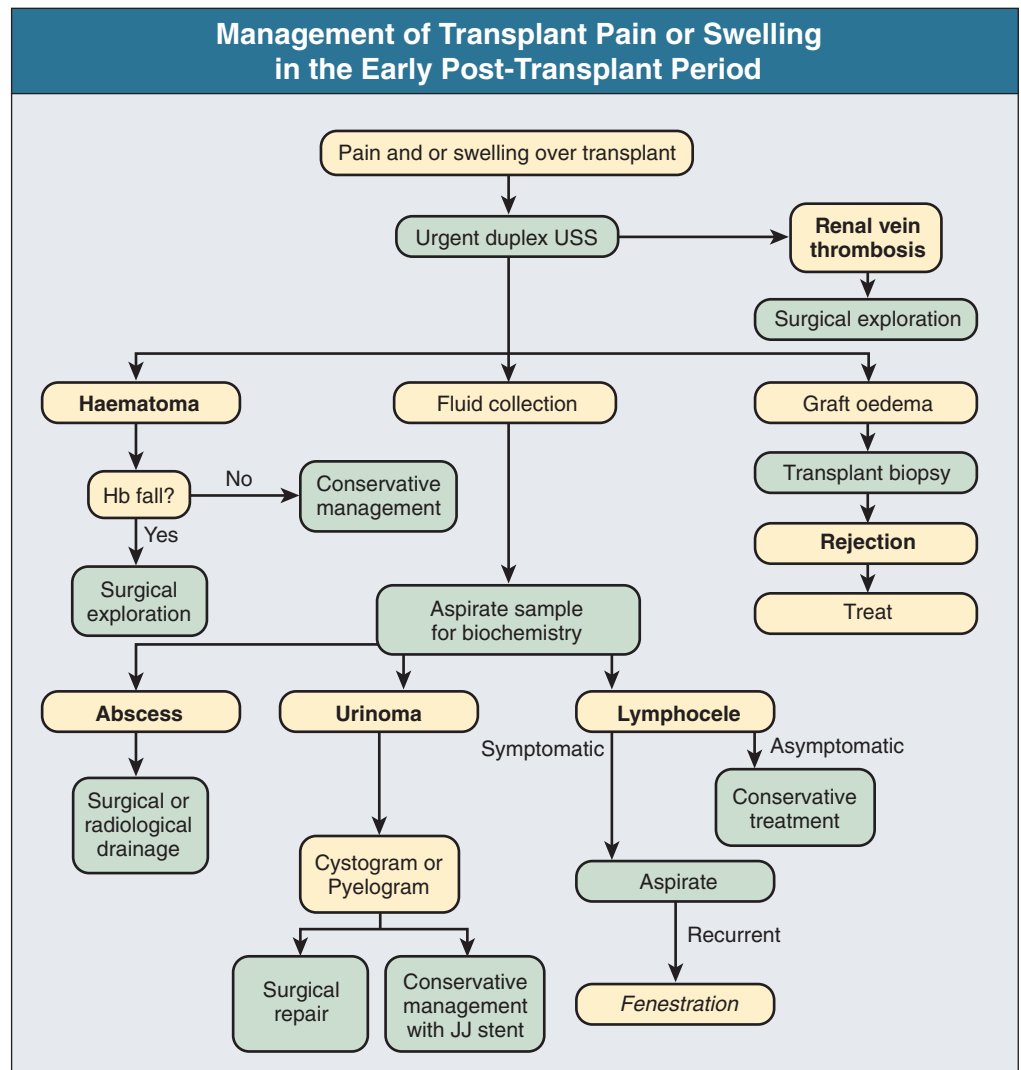

Figure 99.7 Management of sudden oliguria or anuria in the early post-transplantation period. ATN, acute tubular necrosis; CMD, corticomedullary differentiation.

Figure 99.8 Management of transplant pain or swelling in the early post-transplantation period. Hb, hemoglobin; USS, ultrasound scan.

Wound Infection

The use of preoperative prophylactic antibiotics, commonly amoxicillin-clavulanate, has reduced the incidence of wound infection to less than 1%. If a wound infection does occur, treatment is with antibiotics, guided by microbiology from wound swabs, and drainage of collections as necessary.

Wound Dehiscence

The risk of wound dehiscence is increased in obese and diabetic patients and those receiving sirolimus. Identification and treatment of any infection are mandatory. Resuturing of a superficial wound breakdown is rarely justified. Large areas of dehiscence often benefit from vacuum-assisted closure, but the majority require only frequent dressing.

Vascular Complications

Transplant vascular thrombosis is a feared complication that may cause early and irreversible graft failure. Although there are also significant hemorrhagic risks, routine perioperative prophylaxis may be given with subcutaneous low-molecular-weight heparin,

and some units prescribe aspirin for the first few postoperative months.

Bleeding from Vessels in the Renal Hilum

Careful postoperative observations, with regular hemoglobin and hematocrit measurements, are crucial for the early detection of bleeding. Output from the transplant drains may give an early indication of heavy blood loss. Unsecured small vessels in the renal hilum may not be obvious during surgery, but they may start bleeding postoperatively. This form of blood loss can be slow, persistent, and serious. If the patient's condition allows, urgent imaging may be performed to secure a diagnosis, but the best course of action is usually emergency exploration of the transplant under general anesthesia.

Anastomotic Hemorrhage

This is a rare occurrence, usually due to a technical surgical error, and is more common with multiple arteries and use of antiplatelet agents.^{19,20} Early after transplantation, the patient may complain of pain over the graft. This symptom should always be taken seriously. There may also be pain in the back or the rectum caused by a tension hematoma in the retroperitoneum or pelvis. Significant hemorrhage will be attended by

circulatory collapse, with tachycardia and hypotension. There will be a decrease in the hemoglobin and hematocrit, sometimes to alarmingly low levels. The patient must be returned to the operating theater immediately and the transplant re-explored.

Hemorrhage can also occur some weeks after transplantation because of the development of a mycotic aneurysm of the renal artery. In the rare case of a ruptured mycotic aneurysm, an immediate graft nephrectomy is required, but the mortality is high.

Renal Artery Thrombosis

This is a rare event, occurring in less than 1% of transplants. The usual outcome is loss of the kidney. Acute arterial thrombosis may occur intraoperatively or during the first days or weeks after transplantation. Potential causes include hyperacute rejection and a procoagulant state, but most cases are due to a technical error during the anastomosis of small or atheromatous vessels.²⁰ Successful vascular anastomosis requires that the vessels are not under tension and that there is a smooth transition between the two intimal surfaces; sutures must be placed through all layers of the vessel walls so that an intimal flap is avoided. Vascular adventitia is thrombogenic and must be excluded from the lumen of the anastomosis.

Renal artery thrombosis presents with sudden anuria; the differential diagnoses are a blocked urinary catheter, dehydration, acute tubular necrosis, and a urologic complication. A high index of suspicion is required to make this diagnosis, particularly in the immediate postoperative period. The only worthwhile investigation is an urgent duplex ultrasound scan, but if the diagnosis is seriously entertained, then the only hope of saving the transplant is to re-explore it immediately in the hope that a correctable cause can be found. The reality is that unless the acute arterial thrombosis occurs on-table, there is little chance of saving the transplanted kidney. Acutely thrombosed grafts must nevertheless be explored and removed to avoid the development of sepsis in a necrotic graft, a potentially fatal complication.

Renal Vein Thrombosis

Renal vein thrombosis is more common than arterial thrombosis and occurs in 1% to 6% of renal transplants.^{20,21} It may result from a technical error at the time of surgery, but its cause is usually less certain. The renal vein can certainly be twisted or kinked if it is not correctly placed after completion of the vascular and ureteral anastomoses. The peak incidence of renal vein thrombosis is 3 to 9 days after transplantation²²; a transplant with good initial graft function will have a sudden loss of urine output, which is often markedly blood stained, associated with severe pain arising from swelling and (very rarely) rupture of the allograft. The ipsilateral leg may also swell if there is involvement of the iliac venous system. Renal vein thrombosis may also be occult and is one differential diagnosis of delayed graft function. Duplex ultrasound scanning is the best investigation. In an established renal vein thrombosis, this may show an obviously swollen allograft with surrounding hematoma and an absence of renal perfusion. Lesser degrees of thrombosis, or indeed incipient thrombosis, may be highlighted by an absence of arterial flow in diastole. An even later development is a reversal of flow in diastole.

As with arterial thrombosis, if this diagnosis is entertained, the best course of action is to re-explore the transplant as an emergency. The renal vein anastomosis can be opened to allow clot to be extracted, and the venotomy is then closed and the kidney observed for improvement. A more radical alternative is to immediately explant the kidney by taking down the arterial,

venous, and ureteral anastomoses. The kidney can then be reflushed with cold perfusion fluid on the back table and held in preservation fluid at 4°C. This allows much more time to assess the cause of the venous thrombosis, and if the kidney remains viable, the transplant operation can then be repeated. If the transplant is already infarcted or cannot be adequately flushed with preservation fluid, the organ will need to be discarded anyway and nothing is lost by immediate explantation. Successful emergency surgical exploration with subsequent long-term function is rare. Interventional radiographic techniques offer an alternative to surgery. The renal vein can be selectively catheterized through the ipsilateral femoral vein, and graft thrombolysis may then be attempted. This technique is particularly useful when renal vein thrombosis occurs late after transplantation and the risk of systemic anticoagulation is low. The use of various thrombolytic agents has been reported, including heparin, urokinase, streptokinase, and tissue plasminogen activator, with no consensus as to which is the most appropriate.

Transplant Renal Artery Stenosis

Transplant renal artery stenosis is a later complication occurring 3 to 48 months after transplantation. Not all stenoses are of functional or clinical significance, as shown by studies in which all functioning transplants have undergone angiography.²³ Causal factors include donor and recipient atherosclerosis, factors associated with surgical technique, and severe acute rejection.²⁴ The presentation and management of transplanted renal artery stenosis are discussed in Chapter 64.

Lymphocele

Small, clinically insignificant lymphatic collections can be demonstrated by ultrasound scan in up to 50% of renal transplants.²⁵ Larger lymphoceles that cause complications or require treatment occur in 2% to 10% of cases.²⁶ The source of peritransplant lymph leaks is the lymphatic channels around the iliac arterial system rather than the lymphatics of the transplanted kidney itself.²⁷ Therefore, during the dissection of the iliac arterial system, all the surrounding lymphatic channels must be meticulously secured with nonabsorbable ligatures or metals clips. Wound suction drains should not be removed postoperatively until less than 30 ml of fluid is produced on 2 consecutive days. It is safe to leave drains in place for several weeks after transplantation to allow a low-volume lymphatic leak to seal by gradual fibrosis. Despite the theoretical risk of infection, this does not seem to be a problem in practice. If necessary, the patient can be discharged from the hospital with the drain *in situ*.

Compression of the transplanted ureter leading to renal dysfunction is produced only by very large lymphoceles (volume >300 ml). The peak incidence is at 6 weeks, but a lymphatic collection may present between 2 weeks and 6 months after transplantation.²⁵ Most lymphatic collections are found anterior to the iliac vessels and lying between the transplant and the bladder (Fig. 99.9). Presenting features may include wound or ipsilateral thigh swelling in association with suprapubic discomfort and urinary frequency due to bladder compression. Other presentations include pain over the transplanted kidney sometimes associated with fever, ureteral obstruction with graft dysfunction, and ipsilateral thrombophlebitis. However, most are asymptomatic and present as an incidental finding during an ultrasound scan being performed for another reason. It is important to aspirate all peritransplant fluid collections under ultrasound control to aid diagnosis. Macroscopic findings are usually sufficient to

Figure 99.9 Post-transplantation lymphocele. **A**, Ultrasound appearance. A large echolucent lymphocele can be seen inferior to the transplanted kidney. **B**, Computed tomographic appearance. A 5- × 5-cm lymphocele (arrowheads) is present under the transplanted kidney (arrows).

differentiate infected from noninfected lymph, and biochemical analysis of the fluid allows a urine leak to be excluded. Computed tomography or magnetic resonance imaging is an essential investigation if surgery is being contemplated, particularly if a laparoscopic procedure is planned. This allows accurate definition of the relationship between the lymphocele and the transplanted ureter. If the ureter is bow-strung across the superior surface of the lymphocele, it could be damaged during a laparoscopic fenestration procedure.

Many small lymphoceles are asymptomatic and will resolve spontaneously given enough time. If action is deemed necessary, first-line treatment is aspiration under ultrasound control. If there is a recurrence, further aspirations can be performed or an external drain can be placed with ultrasound guidance. If these simple measures fail, open or laparoscopic surgical drainage may be required. A 5-cm-diameter disk of the lymphocele wall is removed to create a large opening into the peritoneal cavity, allowing reabsorption of the lymph through the abdominal lymphatic drainage system. These peritoneal fenestrations have a tendency to heal before the lymphocele is completely reabsorbed, leading to early recurrence; this can be minimized by use of a metal or omental plug.

Urologic Complications

Urinary tract complications are relatively common after renal transplantation, with an incidence of between 5% and 14%.²⁸ Although they can be difficult to manage, they only rarely cause

graft loss or mortality. The relatively high incidence of urologic problems is a consequence of the tenuous blood supply of the transplanted ureter. After kidney retrieval, the only ureteral blood supply that is preserved is derived from the renal artery near the hilum of the kidney, and this can be easily damaged during retrieval.

Urinary Leaks

These most commonly occur because of ischemic necrosis in any part of the transplanted urinary collecting system. The distal ureter has the poorest blood supply and is therefore the most common site. Less commonly, leaks occur from the renal pelvis or the midportion of the ureter, which may be due to unrecognized direct damage to the ureter during organ retrieval. Urinary leaks tend to occur in the first few days after transplantation but can present much later. The usual presentation is with straw-colored fluid leaking directly from the transplant wound or accumulating in the drains in association with oliguria. Alternatively, extravasating urine may accumulate as a peritransplant fluid collection. This presents as a painful swelling of the wound, and the patient may have a fever. In either case, the extravasated fluid must be differentiated from lymph by biochemical analysis of the fluid and a simultaneous serum sample. Urine will have markedly elevated urea and creatinine levels compared with the patient's serum, whereas lymph will have a similar biochemical profile.

The presence of a urinary fistula should be confirmed by antegrade or retrograde pyelography. Both of these techniques present challenges. Antegrade puncture of a nondilated pelvicalyceal system is technically difficult but usually possible. Retrograde cannulation of the transplanted ureteral orifice can be attempted with a flexible cystoscope. This is also a difficult maneuver because the transplanted ureter is implanted into the dome of the bladder rather than at its base. If the urine leak is contained as a urinoma, ultrasound will demonstrate a fluid collection between the transplanted kidney and the bladder that can be sampled by needling or drained by the placement of a suitable percutaneous catheter.

The management of urinary leaks has changed significantly in recent years. The former practice of early re-exploration and surgical reconstruction²⁹ is no longer always necessary. Interventional radiographic techniques offer an alternative, at least for initial treatment. The aim is to place a double-J ureteral stent across the region of damage through an antegrade nephrostomy; this may allow time for the urinary fistula to heal.³⁰ This technique, however, is unlikely to be successful if there is significant ischemic necrosis of the ureter, in which case surgery still has a role. Re-exploration of kidney transplants is straightforward in the early postoperative period but may be a considerable challenge later because of the development of an intense peritransplant fibrotic reaction. The choice of operative procedure for a necrotic distal ureter depends on the length of remaining viable ureter. If there is sufficient length after excision of the necrotic distal portion, the transplanted ureter may be simply reimplanted into the bladder. If this is not possible, the urinary tract should be reconstructed with use of the patient's native ureter (Fig. 99.10). Depending on length of viable transplanted ureter, there is a choice of anastomosis of the native ureter to the transplanted ureter proximal to the ischemic segment (ureteroureterostomy) or to the transplanted renal pelvis (ureteropyelostomy). Whichever technique is chosen, the anastomosis should be protected with a double-J stent. Although these techniques require the native ureter to be ligated proximally, there is usually no need to perform an ipsilateral nephrectomy.³¹ Postoperatively, the

Figure 99.10 Ureteral reconstruction using native ureter.

antegrade nephrostomy can be left *in situ* so that a contrast study can be performed after 7 to 10 days to confirm healing of the new anastomosis. If the transplanted recipient has undergone an ipsilateral nephrectomy in the past or the native ureter is too diseased to be used for reconstruction, a Boari bladder flap can be used to reconstruct the urinary tract.

Ureteral Obstruction

Obstruction of the transplanted ureter may occur at any time after transplantation. It should always be considered in the differential diagnosis of acute transplant dysfunction and excluded by ultrasound examination. The management of transplant ureteral obstruction is summarized in Figure 99.11. Early obstruction is uncommon and suggestive of a technical error, such as creation of a submucosal bladder tunnel that is too tight, kinking of a redundant length of ureter, and incorrect suture placement during anastomosis. Early obstruction may also be caused by blood clot in the ureter, bladder, or catheter. Bleeding may occur from the ureterovesical anastomosis or cystostomy or after a transplant biopsy. It is common practice to drain the urinary bladder with a three-way irrigating catheter as small-diameter two-way Foley catheters are easily blocked by blood clot.

Late ureteral obstruction may occur at the vesicoureteral or pelviureteral junctions. Ischemia that is not severe enough to cause necrosis is presumed to be the cause of most vesicoureteral obstructions. Renal transplants invariably excite a pronounced perigraft fibrotic response, and this is more likely to be the cause of an obstruction at the level of the pelviureteral junction. It is possible that acute rejection episodes contribute to ureteric stenosis, but this has never been unequivocally demonstrated.³²

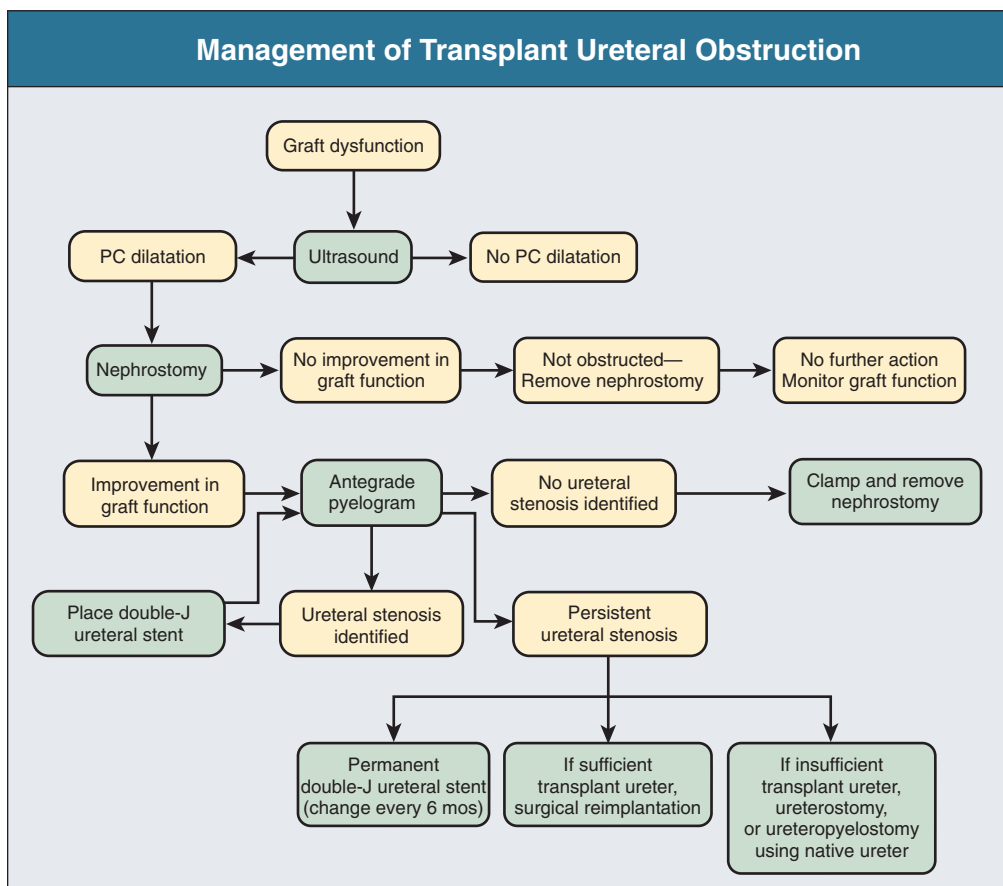

Figure 99.11 Management of transplant ureteral obstruction. PC, pelvicalyceal.

An ultrasound scan will demonstrate a dilated pelvicalyceal system. However, long-standing kidney transplants may have marked pelvicalyceal dilation without being obstructed. This most commonly causes uncertainty in assessing whether obstruction may be contributing to chronic allograft dysfunction in a patient with biopsy-proven chronic allograft nephropathy. Further investigation is needed to confirm or to refute the presence of obstruction and to define its anatomy. Retrograde pyelography has a low success rate because of the difficulty of catheterizing the transplanted ureteral orifice at cystoscopy. Therefore, percutaneous nephrostomy followed by antegrade pyelography is the investigation of choice in suspected transplant ureteral obstruction. The nephrostomy is performed under antibiotic cover using ultrasound control, and the nephrostomy tube should be left in place for a few days. If serum creatinine decreases during this period, obstruction is confirmed. If there is no improvement in renal function, significant obstruction can be confidently excluded. This simple observation avoids the need for an antegrade pressure study (Whittaker test), which may be difficult to interpret in transplanted kidneys. After external decompression of the transplanted kidney for a few days, an antegrade pyelogram is obtained to accurately define the anatomy of the obstructing lesion.

Nonoperative approaches to the treatment of transplant ureteral stricture are often preferred.³³ The simplest approach is to place a double-J stent across the stricture through a percutaneous nephrostomy. This may require initial balloon dilation.³⁴ The stent can be removed after 6 weeks, but the restenosis rate is high. An alternative is long-term stenting, changing the stent every 6 months. The disadvantage of this method is a high incidence of urinary tract infection, with potential severe consequences for immunosuppressed patients, and long-term antibiotic prophylaxis is a sensible precaution. Open surgical management still has a place in the management of ureteral obstruction. The operation performed depends on the site of obstruction and the remaining length of healthy transplanted ureter proximal to the obstruction (see [Urinary Leaks](#)). Not all cases of obstruction require intervention. When there is a mild degree of obstruction not associated with urinary tract infection and in a long-standing kidney that is affected by chronic allograft nephropathy, it may be better to simply monitor transplant function, reserving intervention for a later date should it become necessary.

Complications in the Transplant Bed

A number of nerves may be encountered in the retroperitoneal dissection required for kidney transplantation. These include the lateral femoral cutaneous nerve and the femoral, obturator, and sacral nerves. Each of these may be damaged by a traction injury, particularly when modern fixed wound retraction systems are used as these can exert a great deal of pressure on the surrounding tissues. Such neurapraxias should recover completely, but this may take some months, and they can be very disabling.

In male transplant recipients, the spermatic cord must be mobilized during the dissection to gain access to the retroperitoneal space. Damage to the testicular artery in the cord can result in testicular atrophy.

TRANSPLANT NEPHRECTOMY

An early graft nephrectomy may be required for arterial thrombosis, capsular rupture (due to severe rejection or venous thrombosis), or other technical reasons. Graft nephrectomy may also

be required after graft failure for persisting pain, malaise, fever, and thrombocytopenia, although a nonfunctioning graft left *in situ* will usually shrink and become fibrotic. Early graft nephrectomy is straightforward, but after the first few weeks, kidney transplants usually develop intense perigraft fibrosis, and this can make late allograft nephrectomy a difficult technical challenge. A subcapsular dissection is preferred, and after removal of the kidney, the hilum is sutured, leaving a cuff of donor vessels in place. Careful hemostasis is required, and the whole raw capsular bed should be cauterized. The wound is usually closed without drains.

Prophylaxis and Treatment of Kidney Transplant Rejection

Alexander C. Wiseman

The clinical presentation of the immune response to transplanted tissue, referred to as rejection, became apparent in 1960 when, after successful proof-of-principle kidney transplants were performed in identical twins, kidney transplantation was attempted between immunologically dissimilar individuals.¹ Eleven patients underwent lymphoid irradiation to prevent rejection after kidney transplantation from nonidentical donors. Whereas 10 of 11 died of overwhelming infection, illustrating the potential consequences of immunosuppression, the lone surviving patient from this series subsequently underwent two episodes of acute rejection, both of which were successfully treated with cortisone with successful graft function. Thus began the development of immunosuppressive agents that could prevent and treat rejection while not inducing severe life-threatening side effects and the characterization of the histologic patterns of injury that quantify the type and severity of rejection.

The occurrence of acute rejection in the first year after transplantation has significantly diminished from a nearly universal occurrence of rejection in the earlier era to present-day rates of 10% to 15%,² primarily due to the development of newer immunosuppression medications. Although the incidence of acute rejection has diminished (Fig. 100.1), the management of chronic rejection has remained a challenge, with continued attempts to better define the nature of injury and methods to prevent or to reverse this process. However, as attention shifts to limiting the toxicity of immunosuppression medications in corticosteroid withdrawal and calcineurin inhibitor (CNI) withdrawal protocols and attempts are made to increase access to transplantation by performing transplants across human leukocyte antigen (HLA) and blood type barriers, management of acute rejection will continue to be an important clinical issue. The purpose of this chapter is to summarize our current understanding of rejection from a histologic standpoint and to describe methods for prevention and treatment of this entity.

DEFINITION

Rejection (both acute and chronic) is defined by histologic findings after kidney transplant biopsy. A biopsy considered adequate for analysis involves sampling of at least 10 glomeruli and two small arteries, stained by hematoxylin and eosin, periodic acid–Schiff or silver, and trichrome stains; a biopsy specimen with seven to nine glomeruli and one artery is considered of marginal adequacy. When biopsy is performed for clinical indications (renal dysfunction), two separate cores should be obtained because the findings of rejection are often patchy in distribution (Fig. 100.2).³ There is not a consensus for the number of cores required when biopsies are performed for nonclinical indications

(e.g., in protocol-driven practice), although adequate tissue sampling defined by the preceding criteria is recommended.

The Banff Working Classification of Renal Allograft Pathology forms the basis of the histologic definition of rejection and is reviewed and updated biannually. First developed in 1993 with a primary focus on T cell–mediated acute inflammatory infiltrates to classify the degree of rejection, the most recent (2007) classification (Fig. 100.3) now differentiates a humoral (antibody-mediated) response from the T-cell response and further distinguishes a chronic humoral form of injury previously included within the term *chronic allograft nephropathy* (see Chapter 103).⁴ This has been possible because of the identification of antibody-mediated injury indirectly through evidence of complement deposition. C4d is a fragment of C4b that is generated on IgG and IgM deposition and activation of the classical complement pathway. C4b/C4d forms a covalent bond with proteins on tissue such as capillary endothelial cells through a sulfhydryl group and persists bound to tissue after immunoglobulin and other complement products have been released.⁵ Staining for C4d is currently the most sensitive marker for antibody-mediated injury and should be routinely performed on renal transplant biopsy specimens.

Antibody-Mediated Rejection

Acute antibody-mediated (humoral) rejection is estimated to occur in 3% to 10% of all transplants and is present in 20% to 30% of episodes of acute rejection,⁶ occurring typically within the first few weeks of transplantation or in association with a change in immunosuppression. Whereas patients who have pre-existing donor-specific HLA alloantibodies (donor-specific antibodies) are at higher risk for the development of acute humoral rejection, the identification of *de novo* donor-specific antibodies at the time of graft dysfunction is common. The diagnosis of acute humoral rejection requires (1) evidence of donor-specific antibodies, (2) C4d deposition in peritubular capillaries, and (3) evidence of tissue injury (Fig. 100.4). Patterns of injury associated with acute humoral rejection range from acute tubular cell injury suggestive of acute tubular necrosis (ATN) to thrombotic microangiopathy but typically will be associated with neutrophils or macrophages in peritubular capillaries.

Chronic active antibody-mediated rejection is likely due to an indolent alloimmune response that results in transplant glomerulopathy and arteriolopathy. Although transplant glomerulopathy is often associated with circulating donor-specific antibodies and with C4d deposition, 30% to 50% of cases will be identified in the absence of these diagnostic markers.⁷ This suggests that these lesions are not solely due to a humoral response or that the lack

Figure 100.1 Treatment for acute rejection 1997-2005. (As reported to the Scientific Registry of Transplant Recipients, SRTR Report 2007.)

Figure 100.2 Effect of sample site on the diagnosis of rejection.

Acute rejection begins as patchy, focal infiltrates and becomes homogeneous only in advanced stages. The intensity of mononuclear infiltrate seen on biopsy would differ between core 1 and core 2. Routinely taking two core biopsy samples can help decrease the sampling errors, which can affect the histologic interpretation of rejection.

Classification of Rejection	
Antibody Mediated	
<u>Acute</u>	C4d ⁺ , presence of circulating antidonor antibodies and acute tissue injury
I.	ATN-like (minimal inflammation)
II.	Capillary and/or glomerular inflammation and/or thromboses
III.	Arterial inflammation
<u>Chronic</u>	C4d ⁺ , presence of circulating antidonor antibodies and chronic tissue injury

of a temporal relationship of donor-specific antibodies or C4d deposition to biopsy findings is related to the waxing and waning nature of the humoral response. The diagnosis of chronic humoral rejection requires (1) evidence of donor-specific antibodies, (2) C4d deposition in peritubular capillaries, and (3) evidence of chronic tissue injury. The forms of chronic tissue injury may include duplication of the glomerular basement membrane (GBM), multilamination of the peritubular capillary basement membrane, arterial intimal fibrosis without elastosis, and interstitial fibrosis with tubular atrophy (Fig. 100.5). It has been recommended that if only two of these are present, the diagnosis should be considered “suspicious” for chronic humoral rejection.

T Cell-Mediated Rejection

The classical pathologic description of rejection is now referred to as T cell-mediated rejection. The classification of acute T cell-mediated rejection (acute cellular rejection) is based on the degree and location of mononuclear cell inflammation. Because interstitial inflammation and tubulitis are frequently present immediately beneath the renal capsule (subcapsular inflammation) in stable allografts, this histologic feature is not taken into account in interpreting an allograft biopsy sample for the presence of rejection. When it is severe, interstitial inflammation may extend into tubules by injury to the tubular basement membrane (TBM) (tubulitis). The predominant phenotype of these infiltrates is a mixture of $CD4^+$ and $CD8^+$ T cells; however, B cells, eosinophils, and macrophages may also be present. Less commonly, endarteritis (endothelialitis) may be present, in which T cells and macrophages extend under the arterial endothelium, a phenomenon that may or may not be accompanied by interstitial inflammation or tubulitis. The finding of interstitial infiltrates and tubulitis in a kidney transplant biopsy specimen is not specific to acute cellular rejection, and other causes, such as viral nephropathy (BK virus, less commonly cytomegalovirus [CMV]), pyelonephritis, and post-transplantation lymphoproliferative disease, should be considered on the basis of the clinical presentation. In contrast, the histologic finding of endothelialitis is pathognomonic of acute cellular rejection.

Acute T cell-mediated rejection is histologically classified in the Banff criteria on the basis of the presence or absence of endothelialitis, the degree of interstitial inflammation, and the quantity of infiltrating cells into tubules. Type I acute cellular rejection (Fig. 100.6) is characterized by the absence of endothelialitis, with interstitial inflammation of at least 25% of the parenchyma and tubulitis (type IA requires 4 to 10 mononuclear cells/tubular cross section; type IB requires >10 mononuclear cells/tubular cross section). Type II acute cellular rejection (Fig. 100.7) is characterized by vascular involvement/endothelialitis

Figure 100.6 Type I acute cellular rejection. Type I acute rejection is manifested by interstitial mononuclear cell infiltration (*asterisk*) with invasion of the tubules (*arrow*). (Periodic acid–Schiff; magnification $\times 200$.)

Figure 100.7 Type II acute cellular rejection. Type II rejection, called acute vascular rejection, is manifested by endothelialitis with mononuclear cell infiltration (*arrows*) beneath the arterial endothelium. (Periodic acid–Schiff; magnification $\times 200$.) (Courtesy Dr. Agnes Fogo, Vanderbilt University, Nashville, Tennessee, USA.)

(type IIA requires mild to moderate intimal arteritis; type IIB requires arteritis with at least 25% of the luminal area lost in at least one arterial cross section). Type III acute cellular rejection (Fig. 100.8) is characterized by vascular inflammation that extends to the media (transmural) and may be accompanied by fibrinoid change and necrosis of the smooth muscle cells. Type II and type III acute cellular rejection may or may not be associated with elements of type I acute cellular rejection; thus, the pathologic description of rejection should not be viewed as a pathogenic continuum. However, type II and type III acute cellular rejection appear to require different therapeutic interventions and carry prognostic implications different from those of type I acute cellular rejection (see later sections).

Chronic active T cell–mediated rejection is a histologic diagnosis that refers to arterial intimal fibrosis specifically with evidence of mononuclear cell infiltration and formation of neointima (Fig. 100.9). This is distinguished from chronic humoral rejection by the location of vascular injury and lack of evidence of pathogenic antibody, and it is distinguished from other nonimmunologic processes that may lead to vascular and interstitial fibrosis by the presence of persistent infiltrating cells within vessels. This is covered in greater detail in Chapter 103.

(Hematoxylin and eosin; magnification $\times 200$.) (Photomicrographs courtesy Dr. Maxwell Smith, University of Colorado, Denver, Colorado, USA.)

Borderline Rejection

The finding of inflammation in 10% to 25% of the interstitium with tubulitis of fewer than four cells per tubular cross section is classified as borderline rejection. This currently remains a pathologic definition without clear clinical significance. When it is identified in the setting of graft dysfunction or with other findings such as glomerulitis, the risk of progression to clinical rejection on subsequent biopsies is increased, and thus treatment may be considered.¹¹

CLINICAL MANIFESTATIONS

The clinical presentation of acute rejection is common to both T cell– and antibody-mediated rejection. Patients typically present with a rapid rise in serum creatinine and in severe cases

Differential Diagnosis of Renal Allograft Dysfunction
Week 1 Post-Transplantation
Acute tubular necrosis

may have a decreasing diuresis, weight gain, fever, or graft tenderness. The clinical findings are commonly nonspecific, and other causes of graft dysfunction are often considered at the time of presentation (Fig. 100.10) in the context of an individual's risk for the development of acute rejection (Fig. 100.11). Because of the increase in transplantation of presensitized patients, patients with known donor-specific antibody in desensitization protocols, and ABO-incompatible transplants, approximately 25% of acute rejection episodes now have a humoral component. In acute humoral rejection, there may be features of thrombotic microangiopathy with microangiopathic anemia and thrombocytopenia. If there is immediate cyanosis of the graft on revascularization (hyperacute rejection) or an abrupt decline in urine output and graft tenderness 3 to 14 days after transplantation (delayed

Risk Factors for Acute Rejection

hyperacute or accelerated rejection), donor-specific antibody is implicated. Typically, there is type III acute cellular rejection and interstitial hemorrhage on biopsy.

PROPHYLAXIS AND PREVENTION

Prophylaxis

The primary goal of transplant management is prevention of immunologic graft loss in the early period after transplantation. Over time, the risk for acute rejection diminishes and goals of immunosuppression therapy shift toward considerations of side effects of medications and risks for other events, such as cardiovascular disease (CVD) and malignancy. Therefore, current clinical practice follows a general strategy of intensive immunosuppression and monitoring in the first months after transplantation with a reduction or alteration of treatment after the initial period of risk.

Prevention of Acute T Cell–Mediated Rejection: Induction Therapy

The use of a brief course of potent immunosuppression at the time of transplantation, referred to as induction therapy, has

become a common strategy for the prevention of acute rejection in all transplant recipients, including those at both higher and lower immunologic risk. According to the Scientific Registry of Transplant Recipients (SRTR) Annual Report in 2007, the use of induction therapy overall in the United States has increased from 52% to 80% during the period 2000–2006. For higher risk patients, such as those with prior sensitization (the presence of HLA antibodies quantified by percentage reactivity against a panel of common HLA types, referred to as percent panel reactive antibodies), prior transplantation, or African American ethnicity, induction therapy is usually combined with standard doses of immunosuppression to prevent rejection. For those with lower risk (living donor kidney recipients, primary kidney transplants), induction therapy is often employed in an effort to minimize exposure to maintenance immunosuppression. The use of race as a risk factor for rejection has recently been questioned with a study demonstrating similar acute rejection rates in African Europeans compared with European Caucasians in France.¹² However, most studies still report a higher risk of rejection for African Americans than for American Caucasians; thus, induction therapy is commonly used in this population.¹³

Induction agents can be classified as T-cell depleting or non-depleting. Nondepleting agents include the monoclonal humanized interleukin (IL)–2 receptor antibodies (IL-2Ra) daclizumab (Zenapax) and basiliximab (Simulect). The IL-2 receptor was identified as a potential immunosuppressive target as it is present on T cells and inhibition of IL-2/IL-2R signaling inhibits T-cell proliferation (see Chapter 96). The IL-2Ra have shown a reduction in acute rejection rates with minimal side effects in combination with cyclosporine-based immunosuppression in the absence of mycophenolate.¹⁴ Importantly, these agents have not been studied in a prospective randomized fashion in combination with a tacrolimus/mycophenolate-based maintenance regimen; thus, questions still remain about the relative benefits of the addition of IL-2Ra with more potent, commonly used maintenance agents.

Depleting agents include antithymocyte globulin, OKT3, and anti-CD52. Unlike the IL-2Ra agents, none of these agents has been compared with placebo for the prevention of rejection, and thus their use as induction agents is considered “off label” in the United States. Antithymocyte globulin is a polyclonal preparation of antibodies directed at T cells prepared by immunizing animals with human lymphoid cells derived from the thymus. Earlier preparations were created from equine sources (Atgam), but this preparation is inferior to other depleting agents in the treatment of rejection, and its use has diminished.¹⁵ Currently, the most common antilymphocyte preparation in use is rabbit antithymocyte globulin (rATG, Thymoglobulin). Anti-CD3 (OKT3, muromonab-CD3), a mouse monoclonal antibody directed to the CD3 subunit of the T-cell receptor, also results in depletion of T cells but has fallen out of favor as an induction agent because of a significant innate immune response to foreign antibody that results in a cytokine release syndrome presenting with fevers, hemodynamic changes, pulmonary edema, and, less commonly, seizures.

Recently, use of anti-CD52 (alemtuzumab, Campath-1H) has increased in kidney transplantation. This agent binds to CD52, an antigen of unclear physiologic significance that is present on both B and T cells, and results in depletion of both lymphoid cell lines. Its ability to induce prolonged, significant lymphopenia for up to 6 to 12 months after dosing led to its use in refractory chronic lymphocytic leukemia. Unlike other depleting

agents, it is a humanized antibody and therefore has fewer infusion-related side effects than either antithymocyte globulin or OKT3. Initial trials suggest equivalence to other depleting agents in the prevention of rejection, but the long-term impact of prolonged lymphopenia on the risk for infection or post-transplantation lymphoproliferative disorder has yet to be determined, and comparative trials of induction agents are lacking (see later discussion).

Although effective in the inhibition of the T-cell response, all depleting agents carry concerns for long-term safety. Registry analyses suggest that there is an increased risk of future development of lymphoma with depleting agents compared with nondepleting agents or no induction therapy,^{16,17} an association that appears to be dose dependent. For this reason, repeated or prolonged courses of depleting antibody therapy must be considered with this risk balanced by the potential for graft recovery or prolongation.

Few trials have compared the efficacy of induction agents in the prevention of acute rejection. Recently, a multicenter trial in patients at high risk for acute rejection (patients with an elevated risk of delayed graft function, elevated panel reactive antibodies, repeated transplants, or HLA mismatches) compared the IL-2Ra basiliximab to antithymocyte globulin with maintenance immunosuppression of cyclosporine, mycophenolate mofetil (MMF), and prednisone.¹⁸ At 12 months, the rate of acute rejection in the basiliximab cohort was 26% versus 16% ($P = .02$) in the antithymocyte globulin arm. Whereas the number of infections overall was higher in the antithymocyte globulin arm (86% versus 75%; $P = .03$), the rate of CMV disease was lower with antithymocyte globulin (8%) than with basiliximab (18%; $P = .02$). Thus, for patients at increased risk for rejection, antithymocyte globulin provided greater prevention from acute rejection, supporting its use in higher risk populations. An ongoing clinical trial comparing anti-CD52 to antithymocyte globulin in high-risk patients and IL-2Ra versus antithymocyte globulin in low-risk patients followed by early corticosteroid withdrawal may help clarify the relative benefits of each induction agent. In general, the issues of the need for induction therapy in low-risk patients and the optimal induction agent for high-risk patients are not fully resolved and require further prospective head-to-head trials. Common dosing regimens of induction agents are listed in Figure 100.12.

Prevention of Acute Antibody-Mediated Rejection: Desensitization

The patient who has donor-specific antibodies or is blood type incompatible to the donor before transplantation has a nearly universal risk for development of acute antibody-mediated rejection after transplantation without pretransplantation therapeutic intervention. Experimental protocols have recently emerged that incorporate interventions, referred to as desensitization, that may permit transplantation of these donor-recipient combinations. Desensitization protocols typically involve removal of preformed antibody with plasma exchange and suppression of antibody production and action with intravenous immune globulin (IVIG). These may be coupled with other experimental agents such as rituximab, a humanized anti-CD20 monoclonal antibody that depletes B cells, or splenectomy to reduce B-cell development and thus antibody production.^{19–21} Coupled with depleting antibody induction therapy and standard immunosuppression, acute antibody-mediated rejection rates of 39% have been reported.²²

Figure 100.12 Agents used for induction/desensitization therapy and treatment of rejection. NA, not applicable.

Agents Used for Induction/Desensitization Therapy and Treatment of Rejection			
Agent	Target	Dose (induction)	Dose (rejection)
Methylprednisolone	B cells, T cells, macrophages	500 mg IV intraoperatively, followed by taper during 1–5 days	3–5 mg/kg (250–500 mg) IV × 3–5 days
Basiliximab	IL-2 receptors on T cells	20 mg IV × 2 on days 0, 4	N/A
Dacilizumab	IL-2 receptors on T cells	1–2 mg/kg IV every 2 weeks for 5 doses post-transplantation	N/A
OKT3	CD3 on T cells	5 mg IV × 7–14 days	5 mg IV × 7–14 days
rATG	T-cell surface antigens	1–1.5 mg/kg IV × 4–14 days	1–1.5 mg/kg IV × 7–14 days
Anti-CD52	CD52 on T and B cells	30–60 mg × 1–2 on days 0 and 2	Same as induction
IVIg	B cell inhibition?	1–2 g/kg total dose during 1–5 IV infusions	Same as desensitization
Rituximab	CD20 on B cells	375 mg/m ²	Same as desensitization

Common Immunosuppression Regimens in the United States, 2005		
Regimen	At Time of Hospital Discharge	At One Year Post-Transplantation
<i>Standard Regimens</i>		
TAC/MMF-MPA/Pred	50%	44%
CSA/MMF-MPA/Pred	10%	9%
<i>Avoidance Regimens</i>		
CNI-free (any)	5%	4%
Steroid-free (any)	23%	26%
TAC/MMF-MPA	20%	21%
CSA/MMF-MPA	1%	3%

Figure 100.13 Common immunosuppression regimens in the United States, 2005. CNI, calcineurin inhibitor; CSA, cyclosporine; MMF, mycophenolate mofetil; MPA, mycophenolate sodium; Pred, prednisone; TAC, tacrolimus. (Modified from OPTN/SRTR Annual Report 2007.)

Maintenance Therapy for the Prevention of Acute Rejection

Current maintenance immunosuppression most commonly includes a CNI, an antiproliferative agent, and corticosteroids. This combination of agents forms the standard against which novel strategies are compared, such as corticosteroid withdrawal/avoidance and CNI withdrawal/avoidance. Cyclosporine has been replaced by tacrolimus as the preferred CNI in the United States and together with the antiproliferative agent MMF forms the most common immunosuppressive regimen in current practice in the United States and most Western countries (Fig. 100.13).

Calcineurin Inhibitors in the Prevention of Acute Rejection

Since the early 1980s, when the introduction of cyclosporine resulted in a reduction in the incidence of acute rejection and

improvements in projected graft survival,²³ calcineurin inhibition has been a cornerstone of maintenance immunosuppression. Tacrolimus, first introduced in the 1990s and compared head-to-head with cyclosporine in a number of trials, appears to provide greater protection from acute rejection but with a different side effect profile. A recent meta-analysis of trials that compared tacrolimus- and cyclosporine-based immunosuppression demonstrated a reduction in risk of acute rejection of 31% but an increase in risk for development of diabetes of 86%. Tacrolimus was also associated with a better death-censored graft survival (HR, 0.56), particularly at target trough doses of less than 10 ng/ml, a finding that was not shown in individual studies.²⁴

Antiproliferative Agents in the Prevention of Acute Rejection

The first antiproliferative agent used in kidney transplantation, azathioprine, was introduced in the early 1960s and was used initially in conjunction with corticosteroids and later with cyclosporine. Whereas its development was critical in the advancement of allotransplantation, acute rejection was common, with acute rejection rates of 35% to 40% in a number of clinical trials using cyclosporine/azathioprine/prednisone. Newer antiproliferative agents emerged in the 1990s with MMF and later with sirolimus that significantly reduced the incidence of acute rejection.

MMF, a purine antagonist that interferes with DNA synthesis in rapidly dividing cells such as activated lymphocytes, gained popularity after a number of multicenter prospective clinical trials demonstrated an approximately 50% reduction in the incidence of acute rejection compared with azathioprine.^{25,26} A large registry analysis suggests that there is a beneficial effect of MMF on graft survival, independent of acute rejection.²⁷ One drawback of MMF has been its gastrointestinal tolerability, which often results in reduction of therapy with attendant risks of acute rejection²⁸ and graft loss.²⁹ A mycophenolate analogue, enteric-coated mycophenolate sodium (EC-MPS), has been developed and appears to be “noninferior” in efficacy to MMF,³⁰

with less gastrointestinal side effects reported in one open-label study.³¹

Like MMF, sirolimus was initially tested in clinical trials as a substitute for azathioprine and demonstrated reductions in acute rejection rates similar to MMF.³² An antiproliferative agent that inhibits the progression from G₁ to S phase of the cell cycle, sirolimus appears to have additional antiproliferative effects on nonimmune cells that may contribute to an increase in side effects (impaired wound healing, lymphocele formation, proteinuria, and slower recovery from delayed graft function) but also may reduce the incidence of viral infection and malignant disease.³³

Acute Rejection Rates in Calcineurin Inhibitor- and Corticosteroid-Sparing Immunosuppression Regimens

Given the advances in immunosuppression during the last decade, attempts to eliminate undesirable side effects of immunosuppression have assumed a greater importance in the management of patients. Avoidance of CNIs offers the hope of prolonged graft survival, given the inherent nephrotoxicity of this medication class, whereas avoidance of corticosteroids offers the hope of reducing a number of cosmetic, metabolic, and cardiovascular (CV) side effects attributable to prednisone.

Early corticosteroid cessation (within 7 days after transplantation) has become increasingly popular in the United States. In 2006, more than 30% of all patients were discharged after transplantation without maintenance prednisone therapy. In general, patients at lower immunologic risk (low panel reactive antibodies, first transplants) are selected,^{34,35} and immunosuppression includes induction therapy, a CNI, and an antiproliferative agent. Acute rejection rates in single-center studies range from 10% to 15%. In the largest prospective, multicenter study of corticosteroid cessation to date,³⁶ a standard corticosteroid taper or a rapid elimination of corticosteroids at 7 days after transplantation was compared on the background of induction therapy plus a tacrolimus/MMF-based immunosuppression. Corticosteroid withdrawal was associated with less bone disease, less weight gain, and lower triglyceride levels with similar graft function at 5 years. However, rejection rates were higher in the corticosteroid withdrawal arm (18% versus 11%; $P = .04$), and a *post hoc* analysis suggested a higher rate of chronic allograft nephropathy in the corticosteroid withdrawal arm.

CNI avoidance has been studied with both dual therapy (MMF/prednisone) and triple therapy (sirolimus/MMF/prednisone) with two antiproliferative agents in combination with induction therapy. In general, MMF/prednisone maintenance immunosuppression does not appear to be effective in the prevention of rejection (70% incidence in a pilot study³⁷), and although single-center studies report acute rejection rates of 6% to 13% with sirolimus/MMF/prednisone therapy,^{38,39} a large multicenter trial using this combination and target trough concentrations of sirolimus of 4 to 8 ng/ml also revealed an excessively high acute rejection rate (38%).⁴⁰ Whereas newer agents such as the costimulation blocker belatacept may permit CNI avoidance in the future,⁴¹ and CNI withdrawal with sirolimus 2 to 6 months after transplantation may be more feasible than *de novo* avoidance,^{42,43} CNI-based initial immunosuppression is appropriately considered the standard of care at present.

Acute rejection rates by treatment regimen reported in recent multicenter clinical trials are shown in Figure 100.14. These rates are often higher than rates reported to registries (see Fig. 100.1) because of the more rigorous follow-up and mandatory reporting within the context of clinical trials.

TREATMENT

Acute T Cell–Mediated Rejection

Treatment of T cell–mediated acute rejection is often directed by the findings on biopsy and the clinical response to pulse corticosteroids. For the patient with graft dysfunction and biopsy-proven rejection, treatment with intravenous methylprednisolone, 3 to 5 mg/kg (250 to 500 mg/day), for 3 to 5 days is often effective if the histologic injury is tubulointerstitial (Banff class IA or IB). Remarkably few studies of the clinical response to corticosteroids in the treatment of acute rejection have been performed under modern immunosuppression, but prior data suggest that 60% to 70% of patients will respond with improved urine output and decreasing serum creatinine within 5 days. If there is inadequate response after corticosteroid pulse therapy or if there is vascular involvement (Banff class IIA, IIB), corticosteroids often must be supplemented with T cell–depleting antibody therapies in a similar dosing strategy but longer treatment course compared with their use for induction (see Fig. 100.12). Most studies have used these agents in 7- to 14-day treatment courses, with no clinical trials investigating the efficacy of shorter courses versus longer courses. For patients who are on a maintenance regimen that is not tacrolimus based, tacrolimus conversion may also be considered in the setting of rejection with an inadequate response to corticosteroids⁴⁴; for patients on a corticosteroid-free regimen, reinstitution of maintenance prednisone may be warranted.⁴⁵

The question of the most effective depleting agent for treatment of acute rejection remains a matter of debate. In general, the number and quality of trials comparing agents do not permit firm conclusions. In a meta-analysis of randomized trials comparing monoclonal (OKT3) versus polyclonal (antilymphocyte globulin, antithymocyte globulin) antibody therapy, no differences were noted in reversing rejection, preventing subsequent rejection, or preventing graft loss, whereas OKT3 was three times more likely to induce reactions of fever, chills, and malaise.⁴⁶ Given a more favorable side effect profile, antithymocyte globulin has become the most common antibody agent used in the treatment of refractory rejection. According to the SRTR Annual Report 2007, in 2005 75% of patients with acute rejection were treated with corticosteroids with or without additional agents, whereas 28%, 5%, and 2% of patients were treated with antithymocyte globulin, OKT3, and alemtuzumab, respectively.

Acute Antibody-Mediated Rejection

Treatment of acute humoral rejection is indicated when the triad of graft injury, C4d⁺ staining in peritubular capillaries on biopsy, and circulating donor-specific antibody is present, but it should also be considered in high-risk circumstances (prior desensitization or known donor-specific antibody) even if all three criteria are not met. Treatment entails removal of the pathogenic immunoglobulins with plasma exchange and inhibition/suppression of antibody production with IVIG. In general, at least five plasma exchange treatments should be administered with 1 to 2 g/kg total dose of IVIG. As IVIG is removed by plasma exchange, a common strategy employed is to administer IVIG 100 to 200 mg/kg after each exchange. For refractory acute humoral rejection, rituximab may be considered despite targeting of B cells at an earlier phase of maturation than the antibody-producing plasma cell line.⁴⁷ Finally, there are case reports of splenectomy for refractory acute humoral rejection.⁴⁸ These therapies are typically coupled with targeted T-cell therapy, such as high-dose

Maintenance Immunosuppression and Reported Rejection Rates in Randomized Multi-Center Trials				
Regimen	Induction	CNI Dose or Trough Goal	Antiproliferative Dosing	Acute Rejection at 6 Months
Low Immunologic Risk				
CSA/AZA/Pred		4.0 mg/kg/d	1.5–2 mg/kg/d	36% ²⁶

Mycophenolate trough levels are of limited value. *A higher percentage of living donor kidney transplant recipients were enrolled in this clinical trial. For general comparison only. In comparing acute rejection rates from various clinical trials, the study population and treatment algorithms may be different between trials. AZA, azathioprine; CSA, cyclosporine; IL-2Ra, interleukin-2 receptor antibodies; MMF, mycophenolate mofetil; Pred, prednisone; rATG, rabbit antithymocyte globulin; SRL, sirolimus; TAC, tacrolimus.

corticosteroids or depleting antibody therapy, because helper T-cell function may contribute to an enhanced B-cell response.

Chronic Rejection (T Cell or Antibody Mediated)

T cell- or antibody-mediated injury in a graft without features of acute tissue injury remains a therapeutic dilemma in kidney transplantation. No specific intervention has been proven to be effective in reversing the chronic tissue injury; however, consideration should be given to optimizing or enhancing the maintenance immunosuppression by transitioning to tacrolimus/MMF therapy or increasing the dose of these agents if CNI nephrotoxicity is not identified.⁴⁹ Any intervention should be weighed against the potential for risk of enhanced immunosuppression and the lack of any long-term data describing the impact of enhancing immunosuppression. This topic is discussed in greater detail in Chapter 103.

PROGNOSIS

Episodes of acute rejection may predispose to chronic graft dysfunction, with increased histologic findings of chronic rejection or interstitial fibrosis and tubular atrophy and clinical findings of reduced graft survival. The clinical response to antirejection therapy appears to be critical in this regard, as the change in renal function from 6 and 12 months after transplantation is more predictive of long-term graft survival than the occurrence of prior episodes of acute rejection.⁵⁰ Two analyses (one examining the United States experience⁵¹ and another examining the Australia/New Zealand experience⁵²) have shed light on risk factors for graft loss after episodes of acute rejection. In general, acute T cell-mediated rejection that responds to therapy with return to near-baseline renal function does not portend worse graft survival. However, vascular rejection, late rejection (after 3 months), and rejection that does not respond to within 75% of

baseline serum creatinine level is associated with worse graft outcomes. Although acute rejection rates have fallen significantly during the past decade, graft survival rates have not improved in similar fashion; one explanation for this finding is that the rejection now identified tends to be less responsive to therapy, with fewer cases achieving near-baseline serum creatinine levels. The long-term prognosis after episodes of acute antibody-mediated rejection has not been fully defined in prospective analyses; however, from single-center and retrospective studies, it appears that episodes of acute humoral rejection are likely to have an impact on long-term graft survival. Similarly, the emergence of *de novo* HLA antibodies at any time after transplantation has been shown to be associated with a 5% worse graft survival *per year* compared with those who do not form anti-HLA antibodies.⁵³ For this reason, patients who have suffered episodes of acute rejection must be rigorously monitored with optimization of baseline maintenance immunosuppression. Remaining questions include the value of escalated immunosuppression, such as longer term scheduled antibody therapy, and additional IVIG treatment for those without adequate clinical response or with persistently elevated titers of HLA antibodies.

Medical Management of the Kidney Transplant Recipient: Infections and Malignant Neoplasms

Phuong-Thu T. Pham, Gabriel M. Danovitch, Phuong-Chi T. Pham

Patient and graft survival rates in recipients of solid organ transplants have improved significantly because of refinement in surgical techniques and the advent of potent immunosuppressive agents. Nonetheless, malignant neoplasms and infectious complications continue to adversely affect post-transplantation morbidity and mortality. Although rare, donor-derived infections or malignant disease can arise by delayed donor seroconversion after a recent acute infection, unidentified pathogens in the organ donor, occult neoplastic disease at the time of organ procurement, or malignant transformation of donor cells. This chapter discusses infections and post-transplantation-related malignant neoplasms in recipients of renal transplants. Post-transplantation infectious and drug-related gastrointestinal complications are also discussed.

INFECTIOUS DISEASES

Despite prophylactic therapy against common bacterial, viral, and opportunistic pathogens in the perioperative and postoperative period, infections are the second most common cause of death after cardiovascular disease (CVD) in renal transplant recipients. According to the U.S. Renal Data System (USRDS), infections occurred at a rate of 45 per 100 patient-years during the first 3 years after transplantation.¹ The most common infections are bacterial, followed by viral and fungal. Parasitic infections are rare. Notably, cytomegalovirus (CMV) and herpes simplex virus (HSV) infection rates have decreased since the mid-1990s as a result of effective antiviral prophylaxis; hepatitis B virus (HBV) and hepatitis C virus (HCV) infection rates increased during the same period for unclear reasons.

Infectious Etiologies

Both the type and occurrence of infections in the immunocompromised transplant recipient follow a “timetable pattern” (Fig. 101.1).²

Infection with Transplantation

Although rare, both blood-borne and kidney infections have been transmitted during donation. These include viral infections (e.g., HCV, HBV, human immunodeficiency virus (HIV), CMV, and BK, among others), parasitic infections (malaria, *Babesia*), and bacterial infections (from undiagnosed bacteremia or renal infections).

Month 1 After Transplantation

Most infections in the first month are due to common bacteria and *Candida* acquired in the hospital setting. Except for HSV, other viral infections are uncommon during this period. Similar

to those that follow any major surgical procedure, most bacterial infections during this period involve wounds, catheters, and drainage sites. Aspiration pneumonia and urinary tract infections (UTIs) are common. Infections specific to renal transplant recipients include perinephric fluid collections due to lymphoceles, wound hematomas, or urine leaks; indwelling urinary stents; and UTIs secondary to urinary tract abnormalities, such as ureteral stricture, vesicoureteral reflux, or neurogenic bladder. Most UTIs are caused by common gram-negative bacteria (*Escherichia coli*, Enterobacteriaceae, and *Pseudomonas*) and gram-positive bacteria (enterococcus). Preventive measures for UTIs include early urethral catheter removal and antibiotic prophylaxis. Trimethoprim-sulfamethoxazole or ciprofloxacin prophylaxis during the first 3 months after transplantation effectively reduces the frequency of UTIs to less than 10% and essentially eliminates urosepsis unless anatomic or functional derangement of the urinary tract is present.

Infections with multidrug-resistant microorganisms have recently emerged as an important cause of morbidity and mortality in organ transplantation. Hence, in some centers, the routine use of antibiotic prophylaxis is no longer recommended. Although strict aseptic surgical techniques and perioperative use of first-generation cephalosporins reduce the incidence of wound infections, infections are still observed, especially in subjects with comorbid conditions such as diabetes mellitus (DM) and obesity. Antibiotic-associated *Clostridium difficile* infection (particularly cephalosporins, ciprofloxacin, and amoxicillin-clavulanate) has become a serious epidemiologic problem worldwide. Judicious use of antibiotic prophylactic therapy may decrease the incidence of iatrogenic *C. difficile* infections. Whereas most infections during the first month are due to routine bacterial infections, nosocomial outbreaks have also been reported for rarer infections, such as *Legionella* from contaminated hospital water supplies.

Months 1 to 6

During months 1 to 6, opportunistic infections secondary to immunosuppression are most common. Viral infections, such as CMV, HSV, varicella-zoster virus (VZV), Epstein-Barr virus (EBV), HBV, and HCV, may occur from exogenous infection or reactivation of latent disease due to the immunosuppressed state. Repeated courses of antibiotics and corticosteroid therapy increase the risk of fungal infections, whereas viral infections may not only result from the immunosuppression but may themselves further impair immunity to increase the risk for additional opportunistic infections. Opportunistic infections may occur with *Pneumocystis jirovecii* (previously *Pneumocystis carinii*), *Aspergillus* species, *Listeria monocytogenes*, *Nocardia* species, and *Toxoplasma gondii*. Trimethoprim-sulfamethoxazole prophylaxis (see

Figure 101.1 Timetable of infections.* *Geographically focused infections will need to be considered in certain cases, such as malaria, leishmaniasis, trypanosomiasis, and strongyloidiasis. ¹Sources of infections specific to recipients of renal transplant: perinephric fluid collections (e.g., lymphoceles, wound hematomas, urine leaks), indwelling urinary stents, or anatomic or functional genitourinary tract abnormalities (e.g., ureteral stricture, vesicoureteric reflux, neurogenic bladder). CMV, cytomegalovirus; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HHV, human herpesvirus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus. (Modified from reference 2.)

Timetable of Infections*		
Month 1 After Transplantation	Months 1–6	After 6 Months
Postoperative bacterial infections Urinary tract Respiratory Vascular access related Wound Intra-abdominal infections ¹ Bacteremia Nosocomial , including <i>Legionella</i> species Viral: HSV, HBV, HCV, HIV Fungal: <i>Candida</i> Organisms transmitted with donor organ Untreated infection in recipient	Opportunistic or unconventional infections Viral: CMV, HHV-6, HHV-7, EBV, VZV, influenza, RSV, adenovirus Fungal: <i>Aspergillus</i> species, <i>Cryptococcus</i> , <i>Mucor</i> Bacterial: <i>Nocardia</i> , <i>Listeria</i> , <i>Mycobacterium</i> species, <i>Legionella</i> , tuberculosis Parasitic: <i>Pneumocystis</i> , <i>Jiroveci</i> , <i>Toxoplasma</i> and <i>Strongyloides</i> species, leishmaniasis	Late opportunistic infections <i>Cryptococcus</i> , CMV retinitis or colitis, VZV, parovirus-B-19, polyomavirus BK, <i>Listeria</i> , tuberculosis Persistent infections: HBV, HCV Associated with malignancy EBV, papillomavirus, HSV, HHV-8 Community acquired Unusual sites (e.g., paravertebral abscess)

Fig. 101.2 for trimethoprim-sulfamethoxazole allergy) eliminates or reduces the incidence of *Pneumocystis* pneumonia, *L. monocytogenes* meningitis, *Nocardia* species infection, and *T. gondii* infection.

After 6 Months

After 6 months, the infection risk can be categorized on the basis of the patient's status.

The first category consists of the majority of transplant recipients (70% to 80%), who have satisfactory or good allograft function, relatively low doses of immunosuppression medication, and no history of chronic viral infection. The risk of infection in these patients is similar to that of the general population, with community-acquired respiratory viruses constituting the major infective agents. Opportunistic infections are unusual unless environmental exposure has occurred.

The second group (approximately 10% of patients) consists of those with chronic viral infection that may include HBV, HCV, CMV, EBV, BK virus, or papillomavirus. In the setting of immunosuppression, such viral infections may lead to the development of progressive liver disease or cirrhosis (HBV, HCV), BK nephropathy, post-transplantation lymphoproliferative disease (EBV), or squamous cell carcinoma (papillomavirus).

The third group (approximately 10% of patients) consists of those who experience multiple episodes of rejection requiring repeated exposure to heavy immunosuppression. These patients are the most likely to develop chronic viral infections and superinfection with opportunistic organisms. Causative opportunistic pathogens include *P. jiroveci*, *L. monocytogenes*, *Nocardia asteroides*, and *Cryptococcus neoformans* and geographically restricted mycoses (coccidioidomycosis, histoplasmosis, blastomycosis, and paracoccidioidomycosis). In these high-risk candidates, lifelong prophylactic therapy with trimethoprim-sulfamethoxazole (80 mg/400 mg daily) has been advocated. Lifelong antifungal prophylaxis should also be considered and environmental exposure minimized (primarily avoidance of pigeons and areas of active building construction).

Newly Recognized Viral Infections

Several uncommon viral infections have recently been reported in both the early and late post-transplantation periods.³ In the

early post-transplantation period, outbreaks of donor-transmitted viral infections, such as lymphocytic choriomeningitis and West Nile virus, have been reported. Lymphocytic choriomeningitis occurs within the first 4 weeks after transplantation and is associated with a greater than 90% mortality rate.³ In the late post-transplantation period, infections with community-acquired viral pathogens, including vaccine-preventable diseases such as mumps and measles, have reemerged. There is currently no effective antiviral therapy against either infection, and adherence to current guidelines for vaccinations in solid organ transplantation is recommended (discussed later). Other emerging or reemerging viral infections include adenovirus, human herpesvirus 6, metapneumovirus, parainfluenza, and respiratory syncytial virus. Interestingly, only rare cases due to severe acute respiratory syndrome (SARS) coronavirus have been reported.

The following sections discuss selected infections in renal transplant recipients. Suggested prophylactic therapy is shown in Figure 101.2.

Cytomegalovirus Infection

CMV infection may be a primary infection in a seronegative recipient (donor seropositive, recipient seronegative), reactivation of endogenous latent virus (donor seropositive or seronegative, recipient seropositive), or superinfection with a new virus strain in a seropositive recipient (donor seropositive, recipient seropositive). Primary CMV infection is usually more severe than reactive infection or superinfection.

CMV infection occurs primarily after the first month of transplantation and continues to be a significant cause of morbidity in the first 6 months after organ transplantation through both direct and indirect effects.

Clinical Manifestations

CMV infection may be asymptomatic, presenting as a mononucleosis-like syndrome or influenza-like illness with fever and leukopenia or thrombocytopenia, or a severe systemic disease. Hepatitis, esophagitis, gastroenteritis with colonic ulceration, pneumonia, chorioretinitis (associated with retinal hemorrhage), and even otitis⁴ may occur. In enterically drained pancreas transplantation, CMV has been reported to cause bleeding ulcer from the duodenal segment. Clinical manifestations usually

Suggested Prophylactic Therapy for Recipients of Renal Transplants

Comments	
Trimethoprim-sulfamethoxazole (TMP–SMZ)* (80/400 mg) one tablet daily × 3 months	Its routine use reduces or eliminates the incidence of <i>Pneumocystis jiroveci</i> , <i>Listeria monocytogenes</i> , <i>Nocardia asteroides</i> , and <i>Toxoplasma gondii</i> In renal transplant recipients, TMP–SMZ reduces the incidence of urinary tract infection from 30%–80% to <5%–10%
Monthly intravenous or aerosolized pentamidine > dapsone [†] > or atovaquone [‡]	Replaces TMP–SMZ for patients with sulfa allergies
Nystatin 100,000 units/ml, 4 ml after meals and before bedtime or Fluconazole [§] 200 mg one tablet daily × 2 months	For fungal prophylaxis Close monitoring of cyclosporine or tacrolimus levels when starting and stopping antifungal agents
Acyclovir/valganciclovir/ganciclovir	For CMV prophylaxis, see Figure 101.3

Figure 101.2 Suggested prophylactic therapy for recipients of renal transplants.

*Prophylactic therapy for the first 3 months after transplantation is generally recommended. For patients receiving sirolimus immunosuppression, 1 year of therapy is recommended. [†]Check glucose-6-phosphate dehydrogenase deficiency before initiation of therapy. [‡]In order of efficacy. [§]Fluconazole is recommended for recipients of combined kidney-pancreas or combined kidney-liver transplants.

Consider reinstitution of prophylactic therapy for 3 months after acute rejection episodes requiring intensification of immunosuppression. CMV, cytomegalovirus.

occur 1 to 4 months after transplantation except for chorioretinitis, which occurs later in the transplant course.⁵ Quantitative CMV assays of serum in patients with invasive colitis and gastritis or neurologic disease including chorioretinitis are often negative. Diagnosis in such cases may require invasive testing and biopsies.

Immunomodulating Effects of CMV Infection

CMV infection is associated with immune modulation and dysregulation of helper/suppressor T cells and may be a risk factor for chronic allograft rejection, secondary infection with opportunistic agents (such as *P. jiroveci*, *Candida*, and *Aspergillus*), reactivation of human herpesvirus HHV-6 and HHV-7, and the development of post-transplantation lymphoproliferative disease. CMV infection is also associated with acceleration of HCV infection and the development of new-onset DM after transplantation.⁶

Risk Factors for CMV Infection

Donor and recipient seropositive status and the use of blood products from a CMV-seropositive donor are well-established risk factors for CMV infection. Other factors associated with an increased risk of CMV infection include the use of antilymphocyte antibodies, prolonged or repeated course of antilymphocyte preparations, comorbid illnesses, neutropenia, and acute rejection episodes. Mycophenolate mofetil (MMF) has been reported to increase the risk for CMV viremia and CMV disease in some studies, especially in patients receiving more than 3 g/day. Although the cause-effect of allograft rejection and CMV infection remains conjectural, several studies suggest that one may increase the risk for the other, possibly owing to the release of inflammatory cytokines. Prevention of CMV infection, for example, results in a lower incidence of graft rejection.⁷

Prevention and Treatment

Prophylactic therapy begins in the immediate postoperative period. Preemptive therapy involves treatment of those who are found to seroconvert by quantitative laboratory assays of the

blood, such as CMV DNA polymerase chain reaction (PCR) or pp65 antigenemia during surveillance studies. The former assay is highly specific and sensitive for the detection of CMV viremia. The latter is a semiquantitative fluorescent assay in which circulating neutrophils are stained for nonspecific uptake of CMV early antigen (pp65).

Various prophylactic and preemptive protocols have been developed. Oral acyclovir provides effective CMV prophylaxis solely in recipients of seronegative donor organs. Oral or intravenous ganciclovir or oral valganciclovir provides superior prophylactic or preemptive therapy against primary CMV infection or CMV reactivation. Prophylactic or preemptive therapy should be based on the intensity of immunosuppression (i.e., during antilymphocyte antibody therapy) and the seropositive status of the donor, the recipient, or both. Seronegative individuals who receive organs from latently infected seropositive donors are at greatest risk for primary infection and severe CMV disease. A suggested CMV prophylaxis protocol is shown in Figure 101.3.

Clinical CMV disease is treated with intravenous ganciclovir (5 mg/kg twice daily for 3 weeks, dose adjusted for renal dysfunction) with reduction of immunosuppression, such as withholding of MMF. Treatment is continued until clearance of viremia as assessed by PCR or antigenemia. Anecdotal reports have suggested that calcineurin inhibitor (CNI) to sirolimus switch in conjunction with ganciclovir therapy may be beneficial in patients with apparent ganciclovir-resistant CMV.⁸

In patients with gastrointestinal CMV infection, the use of these assays is unreliable, and repeated endoscopy should be considered to assess response to therapy. In patients who have primary infection and respond slowly to therapy, the addition of CMV hyperimmune globulin (150 mg/kg per dose given intravenously every 3 to 4 weeks for 3 months) may be of benefit.⁵ In patients with tissue invasive disease, intravenous ganciclovir is recommended with conversion to oral therapy when there is evidence of a good response, followed by a 3-month course of oral ganciclovir or valganciclovir prophylaxis.⁵ Whereas oral valganciclovir provides good bioavailability and may be effective in mild CMV disease, it is not recommended for the treatment of

Suggested Cytomegalovirus Prophylaxis Protocol¹

For CMV– recipients of a CMV– organ

Acyclovir 400 mg daily (or valganciclovir 450 mg daily) × 3 months
CMV DNA every 2 weeks × 3 months

For CMV– recipients of a CMV+ organ

During antibody treatment, DHPG² 5.0 mg/kg IV everyday, then following antibody treatment/valganciclovir 900 mg PO everyday × 6 months
If no antibody treatment: valganciclovir 900 mg everyday for 6 months
CMV DNA every 2 weeks × 3 months

For CMV+ recipients of a CMV– organ

During antibody treatment, DHPG 5.0 mg/kg IV everyday, then following antibody treatment, valganciclovir 900 mg PO everyday × 6 months
If no antibody treatment: acyclovir 400 mg daily (or valganciclovir 450 mg daily) × 3 months
CMV DNA every 2 weeks × 3 months

For CMV+ recipients of a CMV+ organ

During antibody treatment, DHPG 5.0 mg/kg IV everyday, then following antibody treatment, valganciclovir 900 mg PO everyday × 6 months
If no antibody treatment: acyclovir 400 mg daily (or valganciclovir 450 mg daily)³ × 3 months
CMV DNA every 2 weeks × 3 months

Figure 101.3 Suggested cytomegalovirus prophylaxis protocol.

¹If CMV status is unknown, give intravenous DHPG until CMV status is determined. ²Dose adjustment for renal function is necessary. DHPG, 9-(1,3-dihydroxy-2-propoxymethyl) guanine. ³Although low-dose valganciclovir, 450 mg daily, has been shown to be effective, the Canadian Society of Transplantation Consensus Workshop on CMV management recommends dosing valganciclovir at 900 mg daily for CMV+ recipients of a CMV+ organ (kidney, liver, pancreas, heart). (From reference 9.)

established CMV disease, and intravenous ganciclovir is required. Cidofovir and foscarnet are alternative therapeutic agents, but in view of their nephrotoxicity and potential synergistic nephrotoxicity with CNIs, they are reserved for use when ganciclovir-resistant strains are clinically suspected.

Candida Infections

Candida infections are common in transplant recipients; *Candida albicans* and *Candida tropicalis* account for 90% of the infections. DM, high-dose corticosteroids, and broad-spectrum antibacterial therapy predispose patients to mucocutaneous candidal infections such as oral candidiasis, intertriginous candidal infections, esophagitis, vaginitis, and UTI. Skin infections are treated with nystatin and topical clotrimazole; candidal UTIs are treated with fluconazole or voriconazole or more rarely with liposomal amphotericin or caspofungin for fluconazole-resistant species (see Chapter 53). Whenever possible, foreign objects such as bladder catheters, surgical drains (e.g., percutaneous nephrostomy tube), and urinary stents should be promptly removed. The ideal management of asymptomatic candiduria in immunocompromised patients remains uncertain (see Chapter 53), but a short course (7 to 10 days) of fluconazole is generally recommended. Systemic antifungal therapy is indicated in the presence of any positive blood culture for *Candida* species.

BK Infection

BK virus is a ubiquitous human virus with a peak incidence of primary infection in children 2 to 5 years of age and a seroprevalence rate of more than 60% to 90% among the adult population worldwide. After primary infection, BK virus preferentially establishes latency within the genitourinary tract and frequently is reactivated in the setting of immunosuppression. In renal transplant recipients, BK virus is associated with a range of clinical syndromes including asymptomatic viruria with or without viremia, ureteral stenosis and obstruction, interstitial nephritis, and BK allograft nephropathy. During the last decade, BK nephropathy has emerged as an important cause of allograft dysfunction after renal transplantation. Most series report that 30% to 40% of renal transplant recipients develop BK viruria, 10% to 20% develop BK viremia, and 2% to 5% develop BK nephropathy. The highest prevalence of BK viruria and viremia occurs at 2 to 3 months and 3 to 6 months, respectively. The risk for development of BK viremia increases when urine viral load is greater than 10^4 copies/ml, whereas BK nephropathy is unusual in the absence of BK viremia. BK nephropathy commonly presents with an asymptomatic rise in serum creatinine during the first post-transplantation year. However, BK nephropathy may occur as early as the first week to as late as 6 years after transplantation. Diagnosis is made by allograft biopsy, which demonstrates BK viral inclusions in renal tubular cell nuclei and occasionally in glomerular parietal epithelium (Fig. 101.4A). There are variable degrees of interstitial mononuclear inflammation (Fig. 101.4B), often with plasma cells, degenerative changes in tubules, and focal tubulitis, which may mimic acute rejection. BK nephropathy often is associated with very focal and sharply demarcated areas of tubulointerstitial inflammation, corresponding to foci of viral infection. Immunohistochemistry (Fig. 101.4C), *in situ* hybridization, or electron microscopy is required to confirm the diagnosis. BK infection and acute rejection may occur simultaneously, and distinguishing between BK nephropathy and acute rejection or the presence of both can be a diagnostic challenge. In late BK nephropathy, few characteristic intranuclear inclusions are seen, and the histologic changes may be indistinguishable from chronic rejection. A histologic classification system for BK nephropathy based on the degree of active inflammation, acute tubular injury, and tubulointerstitial scarring may have prognostic significance.¹⁰ Urine cytology for decoy cells and quantitative determinations of viruria and of viral load in blood have been proposed as surrogate markers for the diagnosis of BK nephropathy.

Treatment strategies include reduction in immunosuppression that involves reduction or discontinuation of MMF and azathioprine with judicious reduction in CNI therapy or other immunosuppressive regimen. Switching from tacrolimus to cyclosporine or to sirolimus (rapamycin) has resulted in resolution of BK nephropathy and viremia or viruria in anecdotal case reports. Switching from CNI to sirolimus may have the added benefit of avoiding the long-term nephrotoxic effect of CNI therapy. Although no approved antiviral drug is available, adjunctive therapy with leflunomide, cidofovir, quinolones, or intravenous immune globulin (IVIG) may be beneficial, especially in patients with progressive allograft dysfunction. Quinolones are preferred by some centers because of low cost and ease of administration; leflunomide is used by others because of its potential simultaneous antiviral and immunosuppressive properties. Cidofovir is highly concentrated in urine and renal tissue, and the use of low-dose cidofovir in BK nephropathy has been reported to be devoid of nephrotoxicity or serious adverse events. Anecdotal

Figure 101.4 BK virus nephropathy. **A**, Prominent intranuclear viral inclusions are present within tubular epithelial cells (arrows). reports have suggested that IVIG may be effective in treating corticosteroid-resistant rejection,¹¹ and its use may be beneficial in patients with concomitant rejection and BK nephropathy or in those with histopathologic changes that are indistinguishable from those of rejection.

Despite treatment, 30% to more than 60% of patients with established BK nephropathy developed progressive decline in renal function with graft loss. Early diagnosis and intervention may improve prognosis. Intensive monitoring of urine and serum for BK by PCR during the first year with preemptive reduction of immunosuppressive therapy may lead to the resolution of viremia and prevent BK nephropathy. In the absence of active viral replication, patients with graft loss due to BK nephropathy can safely undergo retransplantation. Active surveillance for BK virus reactivation after transplantation is recommended. Suggested guidelines for post-transplantation screening and monitoring for BK replication are shown in Figure 101.5.

Other Infections

Tuberculosis (TB) infection in the renal transplant recipient varies according to the prevalence in the general population (e.g., the incidence of TB in transplant recipients has been reported to occur in 0% to 1.3% in the United States, compared with 11% in South Africa and 11% to 14% in India and Pakistan).¹² Most TB infection in the transplant recipient results from reactivation of dormant lesions in the setting of immunosuppressive therapy. Hence, all renal transplant candidates should have a PPD skin test (tuberculin skin test) placed before transplantation. A positive skin test response or a prior history of TB mandates further evaluation to rule out active disease. Isoniazid prophylaxis for a total of 9 months is recommended for those who have a positive skin test response. Of interest, most of the patients who develop TB after transplantation had negative PPD skin test results before transplantation.¹³ Some centers recommend isoniazid prophylactic therapy in selected PPD-negative patients with (1) a history of inadequately treated TB, (2) radiographic evidence of granulomatous disease and no history of adequate treatment, (3) an organ from a PPD-positive donor, or (4) close and prolonged contact with a case of active TB.¹³ In patients with a known history of adequately treated TB infection, we advocate the use of isoniazid prophylaxis for the first 9 months after transplantation and during intensification of immunosuppression. Others, however, have suggested that isoniazid prophylaxis is not indicated for those patients whose TB had been properly treated.¹² Clinical, radiologic, or culture evidence of active TB infection is a contraindication to transplantation. Enzyme-linked immunospot (ELISPOT), which detects T cells specific for *Mycobacterium tuberculosis* antigens, is unaffected by bacille Calmette-Guérin (BCG) vaccination and has become a major advance in TB screening. In some centers, the tuberculin skin test has been replaced by the ELISPOT assays (T-SPOT.TB assay).

A rare but important cause of infection in transplant patients, particularly those from endemic areas such as Southeast Asia, is *Strongyloides*. In the presence of immunosuppression, a “hyperinfection” syndrome may be observed with parasitic pneumonia (Fig. 101.6) and gastrointestinal involvement.

GASTROINTESTINAL DISEASE

Post-transplantation gastrointestinal complications are common and can arise from a variety of causes. Only selected complications are discussed; for a comprehensive review of

Suggested Guidelines for Screening and Monitoring for BK Nephropathy

post-transplantation gastrointestinal complications, readers are referred to Chapter 83 and references 13 and 14.

Drug-Related Gastrointestinal Complications

MMF commonly causes gastrointestinal side effects, including nausea, vomiting, dyspepsia, anorexia, flatulence, and diarrhea. Dose reduction, transient discontinuation of the drug, or dividing the dose into three or four times a day often ameliorates or resolves the symptoms. Switching to the enteric-coated formulation of MMF may improve gastrointestinal tolerability in some patients but has not been consistently shown to be better than the original formulation. A large randomized double-blind study using patient-reported outcomes to assess the impact of gastrointestinal symptoms on patients' health-related quality of life and symptom burden is currently under way. Sirolimus may cause oral mucocutaneous lesions that can be confused with HSV or CMV infection but are culture negative. Drug-related oral ulcers usually resolve after discontinuation of the offending agent. Sirolimus, tacrolimus, and cyclosporine have also been suggested to cause diarrhea in some patients.

Infections

Post-transplantation infections of the gastrointestinal tract may be viral, fungal, or bacterial in etiology. Viral infections are most commonly caused by CMV and HSV; *C. albicans* and *C. tropicalis* are common opportunistic fungal infections. Leukoplakia and post-transplantation lymphoproliferative disorder (PTLD) may develop in patients with EBV infection (PTLD is discussed in a later section). Commonly encountered bacterial pathogens include *Clostridium difficile* and *Helicobacter pylori*.

Cytomegalovirus Infection

CMV can affect any segment of the gastrointestinal tract. Patients may present with dysphagia, odynophagia, nausea, vomiting, gastroparesis, abdominal pain, diarrhea, or gastrointestinal bleeding. Leukopenia and elevated transaminases are common. Persistent or unexplained symptoms of nausea, vomiting, or diarrhea, particularly in the early post-transplantation period or during intensification of immunosuppression, warrant further investigation with upper or lower endoscopies and biopsies.

Herpes Simplex Virus Infection

HSV infection results primarily from reactivation of endogenous latent virus, causing clinical infection within the first 1 to 2 months after transplantation. Patients commonly present with oral mucocutaneous lesions or gingivostomatitis with or without odynophagia and dysphagia. HSV esophagitis has been noted to occur in patients receiving high-dose corticosteroids and anti-lymphocyte preparations for acute rejection. Limited oral mucocutaneous lesions are treated with oral acyclovir; extensive infections require intravenous acyclovir or ganciclovir. Rare cases of HSV hepatitis have been reported.¹⁴ The routine use of acyclovir prophylaxis in the early post-transplantation period is recommended.

Fungal Infections

Candida stomatitis and esophagitis are common during the first 6 months after transplantation and are increased in subjects with leukopenia or with severe immunosuppression, diabetes, or concomitant infections. Bleeding or perforation with formation of tracheoesophageal fistulas has been reported. Prophylactic oral

nystatin "swish and swallow" during the first month after transplantation is recommended. In high-risk candidates, including liver or pancreas transplant recipients and those receiving anti-lymphocyte antibody therapy, fluconazole prophylactic therapy (3 to 6 months) is warranted.

Clostridium Infection

Clostridium difficile infection may be asymptomatic or present with diarrhea, intestinal obstruction, or even fulminant pseudomembranous colitis with toxic megacolon and perforation. *C. difficile* colitis is reported in 3.5% to 16% of transplant recipients.¹⁵ Risk factors include young (<5 years) or advanced age, female gender, use of monoclonal antibodies to treat acute rejection episodes, and intra-abdominal graft placement. Among transplant recipients receiving antimicrobial therapy, *C. difficile*-associated diarrhea develops in approximately 50% of patients.¹⁵ In mild cases of *C. difficile* infection, oral metronidazole is as effective as oral vancomycin and is the preferred first-line treatment. Treatment failure, however, requires treatment with oral vancomycin. In severely ill patients with gastrointestinal dysmotility or ileus, in which oral agents may not reach the colonic mucosa, metronidazole should be administered intravenously. Severe colonic disease refractory to medical treatment may necessitate colectomy.

Helicobacter Infection

Helicobacter pylori infection is associated with a wide range of gastrointestinal complications including chronic gastritis, duodenal and gastric ulcers, mucosa-associated lymphoid tissue (MALT) lymphoma, and gastric carcinoma, both in the general population and in recipients of solid organ transplants. Treatment includes a triple-drug regimen consisting of two antibiotics and an acid-suppressive agent such as an H₂ blocker or a proton pump inhibitor. The first-line *H. pylori* regimen as recommended by the American College of Gastroenterology is shown in Figure 101.7. In recipients of orthotopic heart transplants, triple-drug therapy resulted in a lower eradication rate compared with the general population, suggesting that immunosuppression may hinder the clearance of *H. pylori*. Unexplained dyspeptic or reflux symptoms should be investigated further with endoscopy and biopsy to exclude malignant transformation. *H. pylori* is now recognized as a risk factor for MALT lymphoma, which may occur in kidney, liver, and heart transplant recipients. In renal transplant recipients infected with *H. pylori*, MALT lymphoma may be less aggressive than other lymphomas, and the disorder may be cured by eradication of *H. pylori*.

Colon Disorders

Post-transplantation colonic complications, such as diverticulitis and colonic perforation, may be life-threatening and difficult to diagnose because symptoms may be masked by immunosuppressive therapy, particularly in the early postoperative period. Diverticulitis complicated by perforation, abscess formation, phlegmon, or fistula has been reported to occur in 1.1% of renal transplant recipients¹⁶ and may be increased in patients with polycystic kidney disease (PKD).

Early post-transplantation colonic perforations are largely due to high-dose corticosteroids, diverticulitis, CMV colitis, and intestinal ischemia; perforations occurring late or years after transplantation are commonly due to diverticulosis or malignant disease. Abdominal symptoms may be absent because of the effects of immunosuppression and may only be suggested by the

Figure 101.7 First-line treatment regimens for *Helicobacter pylori* as recommended by the American College of Gastroenterology. *For patients who have not previously received a macrolide antibiotic. †For patients who have not previously received a macrolide antibiotic or who are intolerant of bismuth quadruple therapy. PPI, proton pump inhibitor.

First-Line Treatment Regimens for <i>Helicobacter pylori</i> as Recommended by the American College of Gastroenterology	
Penicillin allergies	
No*	Standard-dose PPI twice daily (or esomeprazole once daily) + clarithromycin 500 mg twice daily + amoxicillin 1000 mg twice daily for 10–14 days
Yes†	Standard-dose PPI twice daily + clarithromycin 500 mg twice daily + metronidazole 500 mg twice daily for 10–14 days
Yes	Bismuth subsalicylate 525 mg orally 4 times daily + metronidazole 250 mg orally 4 times daily + tetracycline 500 mg orally four times daily + ranitidine 150 mg orally twice daily (or standard-dose PPI once daily to twice daily) for 10–14 days

presence of tachypnea and tachycardia. Mortality after colonic perforation is high. Management includes prompt exteriorization of the perforated colon, early and broad-spectrum antimicrobial therapy, and minimization of immunosuppressive therapy. Although uncommon, the presence of abdominal pain and gastrointestinal bleeding with unexplained fevers or weight loss should raise the suspicion for gastrointestinal TB. The characteristic endoscopic findings include circular ulcers, small diverticula, and sessile polyps. The presence of caseating granulomas or acid-fast bacilli, or both, confirms the diagnosis.

Immunizations Before and After Transplantation

All potential renal transplant candidates should receive immunization for hepatitis B, pneumococcus, and other standard immunizations appropriate for age. Up-to-date recommendations for routine adult immunizations are available through the Centers for Disease Control and Prevention website (www.cdc.gov/nip/rec/adult-schedule.pdf). Immunizations should ideally be administered at least 4 to 6 weeks before transplantation to achieve optimal immune response and to minimize the possibility of live vaccine-derived infection in the post-transplantation period. Household members, close contacts, and health care workers should also be fully immunized.

Live virus or live organism vaccines should be avoided after transplantation. These include measles-mumps-rubella (MMR), live oral poliovirus (which is also contraindicated for household contacts), smallpox (vaccinia), varicella, yellow fever, adenovirus, live oral typhoid (Ty21a), BCG, and intranasal influenza vaccine. In addition, exposure to persons who have chickenpox or herpes zoster should be avoided until the lesions have crusted over and no new lesions are appearing. Vaccinations using inactivated or killed microorganisms, components, and recombinant moieties are safe for transplant recipients. These include hepatitis A and hepatitis B, intramuscular influenza A and B, pneumococcal, *Haemophilus influenzae* b, inactivated poliovirus vaccine, diphtheria-pertussis-tetanus (DPT), and *Neisseria meningitidis*.

In general, vaccination should be avoided in the first 6 months after transplantation because of the potential for stimulating the immune response, with a higher chance of graft dysfunction and rejection. In addition, vaccinations within the first 6 months after transplantation are often ineffective because of heavy immunosuppression. For prevention of infection in adult travelers after solid organ transplantation, readers are referred to reference 17. Recommended vaccinations before and after transplantation are listed in Figure 101.8.

Recommended Immunizations Before and After Transplantation		
Vaccine	Pre	Post
Measles-mumps-rubella	X	–
Diphtheria-tetanus-pertussis	X	Diphtheria and tetanus ^a
Varicella	X	Controversial

TRANSPLANT-ASSOCIATED MALIGNANT NEOPLASMS

Recipients of organ transplants are at increased risk for development of neoplasms compared with the general population. Similar to post-transplantation infectious complications, the time to occurrence of different types of malignant neoplasms after transplantation appears to follow a timetable pattern. The Israel Penn International Transplant Tumor Registry data on the time of appearance of different neoplasms after solid organ transplantation are shown in Figure 101.9. PTLD generally occurs early after transplantation; skin cancers occur with increasing frequency with time. The intensity and duration of immunosuppression as well as the ability of these agents to promote replication of various oncogenic viruses are important risk factors. The associations between human papillomaviruses and cervical and vulvar carcinoma, EBV and PTLD, HBV and HCV and hepatocellular carcinoma, and HHV-8 and Kaposi's sarcoma are well established. Figure 101.10 provides a summary

Time of Appearance of Neoplasms After Transplantation and Initiation of Immunosuppression	
Type of Cancer	Median (months)
Lymphomas	12
Kaposi's sarcoma	13
Carcinomas (excluding Kaposi's)	41
Carcinomas of cervix	46
Hepatobiliary carcinomas	68
Skin cancers	69
Carcinoma of vulva or perineum	114
All cancers	46

Figure 101.9 Time of appearance of neoplasms after transplantation and initiation of immunosuppression.

Meta-Analysis Standardized Incidence Ratios for Cancers Related to Infections in Transplant Recipients	
Cancers	Meta-Analysis SIRs
EBV-related cancers	
Hodgkin's lymphoma	3.89 (2.42–6.26)
Non-Hodgkins lymphoma	8.07 (6.40–10.2)
HHV-8-related cancers	
Kaposi's sarcoma	208.0 (114–369)
HBV/HCV-related cancers	
Liver	2.13 (1.16–3.91)
HPV-related cancers	
Cervix uteri	2.13 (1.37–3.30)
Vulva and vagina	22.8 (15.8–32.7)
Penis	15.8 (5.79–34.4)
Anus	4.85 (1.36–17.3)
Oral cavity and pharynx	3.23 (2.40–4.35)
Non-melanocytic-related skin	28.6 (9.39–87.2)

Figure 101.10 Meta-analysis standardized incidence ratios (SIRs) for cancers related to infections in transplant recipients. EBV, Epstein-Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HHV, human herpesvirus; HPV, human papillomavirus. (Modified from reference 18.)

of the incidence of cancers related to infections in transplant recipients.¹⁸

An analysis of the USRDS database¹⁹ documented that the cancer rates for most common cancers, such as colon, lung, prostate, stomach, esophagus, pancreas, ovary, and breast, are nearly twofold higher after kidney transplantation compared with the general population. Although registry studies have limitations, all transplant recipients should adhere to standard cancer surveillance appropriate for age (Fig. 101.11).²⁰ In patients with a history of pre-transplantation malignant neoplasms, close monitoring for recurrences in the post-transplantation period is mandatory. The highest recurrence rates have been observed with multiple myeloma (67%), non-melanoma skin cancers (53%), bladder carcinomas (29%), sarcomas (29%), symptomatic

renal cell carcinomas (27%), and breast carcinomas (23%).²¹ In an analysis of registry data involving 90 patients with a history of pretransplantation prostate adenocarcinoma (77 renal, 10 heart, and 3 liver transplant recipients), prostate cancer recurrences were found to relate to the stage of disease at initial diagnosis.²² Tumor recurrence rates were 14%, 16%, and 33% for stage I, stage II, and stage III diseases, respectively. Hence, a longer waiting time may be necessary for more advanced disease. Suggested guidelines for tumor-free waiting periods for common pretransplantation malignant neoplasms are shown in Figure 101.12.

Post-Transplantation Lymphoproliferative Disorder

PTLD is the most common post-transplantation malignant neoplasm in children; in adults, it is the second most common malignant neoplasm after skin cancer. PTLD has been reported to occur in 1% to 5% of renal transplant recipients.

The majority of PTLD is non-Hodgkin's lymphoma of B-cell origin, and more than 80% to 90% are linked to EBV infection. Based on the World Health Organization classification, PTLD can be divided into three distinct morphologic groups: (1) diffuse B-cell hyperplasia, (2) polymorphic PTLD (usually monoclonal), and (3) monomorphic PTLD that includes high-grade invasive lymphoma of B- or T-lymphocyte centroblasts. Diffuse B-cell hyperplasia is usually seen in children and young adults and commonly occurs within the first year after transplantation. Polymorphic PTLD represents the most common type of PTLD in both children and adults and may occur at any time after transplantation. In contrast, monomorphic B-cell PTLD is often seen several years after transplantation and may resemble non-Hodgkin's lymphoma in the general population. In a retrospective analysis of registry data for 402 recipients of kidney transplants, PTLD occurred at a median of 18 months (range, 1 to 310 months) after transplantation.

PTLD may present with constitutional symptoms such as fevers, night sweats, and weight loss or localized symptoms of the respiratory tract (infection or mass, including tonsillar or even gingival involvement), gastrointestinal tract (diarrhea, pain, perforation, bleeding, mass), or central nervous system (CNS) (headache, seizure, confusion). In contrast to lymphomas in the general population, in which lymph nodes are almost always involved, lymph node involvement is absent in more than 80% of patients with PTLD.

Risk factors for PTLD include primary EBV infection, younger age, antecedent history of CMV disease, and use of antilymphocyte antibody (e.g., antithymocyte globulin, OKT3). A history of pretransplantation malignant disease and fewer HLA matches are associated with an increased risk of PTLD. Cyclosporine and tacrolimus may enhance the development of EBV-associated PTLD by directly promoting the survival of EBV-infected B cells, presumably through the inhibition of EBV-transformed cells from apoptosis.²³

Reduction or discontinuation of immunosuppressive therapy, particularly antilymphocyte antibody, cyclosporine, tacrolimus, or MMF, is recommended as first-line treatment; prednisone is increased to 10 to 15 mg daily to prevent allograft rejection. Sirolimus has a strong antiproliferative effect on PTLD-derived B-cell lines,²⁴ but whether sirolimus may limit B-cell lymphoma growth while simultaneously providing immunosuppression to prevent graft rejection awaits studies. Acyclovir or ganciclovir therapy and reduction in immunosuppression are beneficial and may be curative in benign polyclonal B-cell proliferation. The

Figure 101.11 Preventive care recommendations for cancer surveillance in renal transplant recipients.

¹As recommended by the American Transplant Society and the European Best Practice Guidelines on renal transplantation. ²The American College of Preventive Medicine recommends regular screening for high-risk individuals but none for low-risk individuals. ³Recommended for African Americans, family history of prostate cancer, patients receiving chronic immunosuppression for organ transplantation. FOBT, fecal occult blood testing; Flex sig, flexible sigmoidoscopy; PSA, prostate-specific antigen. (Sources: *The 2001 Cleveland Clinic Foundation Cancer Surveillance Task Force* and reference 20.)

Preventive Care Recommendations for Cancer Surveillance in Renal Transplant Recipients			
Screening For	Starting at Age	Preventive Care	Screening Frequency
Colorectal cancer	Average risk: 50 years	Colonoscopy or FOBT + Flex sig ¹	Colonoscopy: every 10 years FOBT ¹ : every year Flex sig ¹ : every 5 years
	Increased risk: 40 years	Colonoscopy	Every 5 years if a parent or sibling had colorectal cancer at <60 years of age
		or	At 10 years younger than the youngest family member with cancer
		or	Every 10 years if the relative was 60 years
		or	Consider referral to medical genetics if two or more first degree relatives had colorectal cancer
Skin cancer ¹	Monthly self examination of skin, total-body skin examination every 6 to 12 months by qualified physicians and dermatologists ²		
Females			
Breast cancer	50–69 ¹ years	Breast examination and screening mammography	Every 1 or 2 years
	40–49 ¹ years	Breast examination and screening mammography	Every 1 or 2 years (no evidence for or against for this age group)
	Before age 30 years (if mother or sister had breast cancer)		
Cervical cancer	Once sexually active	Pap smear and pelvic examination	Every year
Males			
Prostate cancer	50 years	Digital rectal examination	Every year
	40 ³ years	PSA testing	Frequency for testing is not established

role of antiviral therapy in B-cell monoclonal malignant transformation is less well defined; 50% to 90% mortality has been reported despite antiviral therapy. Surgical resection with or without adjunctive local irradiation has been suggested for localized disease. Local irradiation has been advocated as the treatment of choice for PTLT involving the central nervous system.

In lesions not amenable to surgery or more aggressive monoclonal types of PTLT, chemotherapy has been used with favorable results compared with reduction in immunosuppression alone. The most frequently used regimens are CHOP (cyclophosphamide, doxorubicin [Adriamycin], vincristine, and prednisone) and VAPEC-B (doxorubicin, etoposide, cyclophosphamide, methotrexate, bleomycin, and vincristine). Other reported promising novel therapies include ProMACE-CytaBOM (prednisone orally, doxorubicin, cyclophosphamide, etoposide-cytarabine, bleomycin, vincristine [Oncovin], methotrexate).²⁵ Adverse effects of chemotherapy include high mortality rates from sepsis and treatment-related toxicities. Rituximab, a chimeric monoclonal antibody with murine variable regions targeting the CD20 antigen and human IgG1- κ constant regions, has antitumor activity against CD20-expressing B-cell lymphomas. Early experiences with rituximab (two to six weekly doses

of 375 mg/m²) in patients with PTLT (in conjunction with reduction in immunosuppression) have shown promising results. Complete remission rates of 30% to 60% have been reported.²⁴ Although the response rates appear to vary substantially among patients and centers, rituximab in conjunction with reduction in immunosuppression is evolving as the treatment of choice for CD20⁺ PTLT. The role of cytokine-based therapy, such as interferon alfa and anti-IL-6, remains poorly defined²⁵; increased risk of allograft rejection is seen with anti-IL-6 treatment. Sirolimus, an immunosuppressant with antiproliferative properties, has been demonstrated to prevent proliferation of B-cell (but not T-cell) PTLT-derived tumor cell lines *in vitro* and *in vivo*.²⁶ Limited data from nine European transplant centers have shown tumor regression in 15 of 19 patients with PTLT who underwent minimization or withdrawal of CNIs and sirolimus conversion.²⁷

Factors that adversely affect survival include multiple- versus single-site involvement, increasing age, B-cell predominance, use of antilymphocyte globulin or antithymocyte globulin and OKT3, and “early” versus “late” onset (within 6 to 12 months versus more than 12 months). In recipients of renal transplants with PTLT restricted to the allograft alone, transplant nephrectomy may improve survival.

Suggested Tumor-Free Waiting Periods for Commonly Encountered Pretransplantation Malignant Neoplasms	
Cancer Type	Waiting Period
Renal	
Incidental, asymptomatic	None
Large, infiltrating	At least 2 years
Wilms' tumor	At least 2 years
Bladder	
<i>In situ</i>	None
Invasive	At least 2 years
Uterus	
<i>In situ</i> cervical	None
Invasive cervical	5 years
Uterine body	At least 2 years
Breast [†]	At least 5 years
Colorectal [‡]	At least 5 years
Prostate	At least 2 years
Lymphoma	At least 2 years
Lung cancer	At least 2 years
Skin	
Melanoma [§]	At least 5 years
Squamous cell	Surveillance
Basal cell	None

Figure 101.12 Suggested guidelines for tumor-free waiting periods for commonly encountered pretransplantation malignant neoplasms. Consultation service is available through the Israel Penn International Transplant Registry website, www.ipitr.org. [†]Early *in situ* (e.g., ductal carcinoma *in situ*) may require only a 2-year wait. Individuals with advanced breast cancer (stage III or IV) should be advised against transplantation. [‡]In patients with localized disease (Dukes' stage A or B1), a 2- to 5-year waiting period may be sufficient. [§]*In situ* melanoma may require a shorter waiting period of 2 years (dermatology consultation is probably warranted).

Skin Cancers

Skin cancers are the most common *de novo* post-transplantation tumors in the adult transplant population and may occur 20 to 30 years earlier in immunosuppressed patients compared with the general population. The incidence of skin cancers is 20 times higher in sun-exposed areas and 7 times higher in non-sun-exposed areas. The use of sirolimus, an inhibitor of mammalian target of rapamycin (mTOR)-induced signaling, may delay the onset or reduce the incidence of post-transplantation skin and non-skin malignant neoplasms (discussed under management of post-transplantation malignant neoplasms).^{28,29}

Risk factors for skin cancer include light skin color, intensity of sun exposure (ultraviolet light exposure), genetic factors, and duration of follow-up after transplantation. In addition, immunosuppression in combination with enhanced sunlight exposure may induce malignant changes in papilloma-induced warts.

Management of Immunosuppressive Therapy in Post-Transplantation Malignant Neoplasms

There is no consensus on the management of immunosuppressive therapy in patients with post-transplantation malignant

neoplasms. It has been proposed by experts in the field that immunosuppression dose reduction or withdrawal may permit recovery of the immune system and control the progression of life-threatening malignant neoplasms. The former allows intact immune surveillance against malignant cells. Nonetheless, this approach is not without its attendant risk of graft rejection and graft loss. Furthermore, little is known as to how much and to what extent immunosuppression reduction or withdrawal might alter the natural history of established post-transplantation malignant neoplasms. In our opinion, CNI to sirolimus switch or CNI minimization in conjunction with sirolimus may be a viable therapeutic option (the antitumoral effect of sirolimus is discussed later). In patients with metastatic cancer, manipulation of immunosuppression is probably futile, and the risk of rejection and graft loss necessitating a return to dialysis is likely to outweigh the benefit.

Studies suggest that immunosuppressive agents have different effects on cancer risk after transplantation. The carcinogenic effects of OKT3, antithymocyte globulin, cyclosporine, tacrolimus, and azathioprine have been well documented. In contrast to azathioprine, MMF has been shown to have antiproliferative effects and has been suggested to protect against post-transplantation malignant neoplasms.^{30,31} Analysis of more than 17,000 adult patients with preexisting DM indicated a significantly higher incidence of malignant transformation in azathioprine-treated than in MMF-treated patients (3.7% versus 2.2%; $P < .01$).³¹ However, whether MMF is protective of post-transplantation malignant neoplasia remains speculative.

Both preclinical and clinical studies have demonstrated that mTOR inhibitors such as sirolimus and everolimus have antiproliferative and antitumor effects. Early studies in renal transplant recipients demonstrated a lower incidence of skin cancer with sirolimus-based therapy without cyclosporine or sirolimus maintenance therapy after early cyclosporine withdrawal compared with those who remained on cyclosporine and sirolimus combination therapy. It has been suggested that the protective effect of sirolimus against skin cancer is due to its inhibition of several ultraviolet light-induced mechanisms involved in skin carcinogenesis. The 5-year malignancy data of the Rapamune Maintenance Regimen trial demonstrated a lower incidence of both skin and non-skin cancers at 5 years after transplantation in recipients receiving sirolimus-based therapy and cyclosporine withdrawal at month 3 compared with those receiving sirolimus and cyclosporine combination therapy.²⁹ Sirolimus therapy has also been reported to result in successful clinical and histologic remission of Kaposi's sarcoma in renal transplant recipients.³² Although sirolimus appears to provide satisfactory outcomes in certain cancers after transplantation, its use in the management of malignant disease after solid organ transplantation remains to be defined and should be tailored to each individual patient.

Medical Management of the Kidney Transplant Recipient: Cardiovascular Disease and Other Issues

Phuong-Thu T. Pham, Gabriel M. Danovitch, Son V. Pham

Although renal transplantation improves both survival and quality of life of the patient compared with dialysis, various medical issues can arise in the transplant recipient. This chapter provides an approach to the medical management of transplant-related complications. Infections and malignant neoplasms are discussed in Chapter 101.

CARDIOVASCULAR DISEASE

Death with a functioning graft is one of the major causes of late graft loss, with cardiovascular (CV) disease being the most frequent cause. Compared with the general population, CV mortality in transplant recipients is increased by nearly 10-fold among patients within the age range of 35 to 44 years and at least doubled among those between the ages of 55 and 64 years. Although renal transplantation ameliorates some CV risk by restoring renal function, it introduces new CV risks, including impaired glucose tolerance or diabetes mellitus, hypertension, and dyslipidemia that are derived, in part, from immunosuppressive medications. Renal transplant recipients have both conventional and unconventional CV risk factors (Fig. 102.1).^{1,2}

Conventional Cardiovascular Disease Risk Factors

Post-transplantation Hypertension

Hypertension is a risk factor for both CV disease and kidney graft failure. The Collaborative Transplant Study (CTS) registry has documented a graded risk for graft failure with increasing levels of systolic and diastolic blood pressure.³ Whether aggressive lowering of blood pressure retards the progression of graft failure similar to the delayed progression of renal disease in the general population with chronic kidney disease (CKD) remains to be studied. Hypertension is common after transplantation and is present in 50% to 90% of renal transplant recipients.^{4,5} The wide range in the frequency may reflect the variable definitions of hypertension, donor source, immunosuppressive medications, time after transplantation, and level of graft function. Systolic blood pressure is highest immediately after transplantation and declines during the first year.⁴ In the CTS registry, only 8% of transplant recipients had a systolic blood pressure below 120 mm Hg at 1 year; 33% had a blood pressure in the prehypertension range; 39% had stage 1 hypertension; and 20% had stage 2 hypertension despite antihypertensive therapy.³ Pre-existing hypertension, tacrolimus and to a greater degree cyclosporine, corticosteroids, quality of donor organ, delayed graft function, chronic allograft nephropathy, high body mass index (BMI) or excess weight gain, acute rejection episodes

independent of creatinine clearance, recurrent or *de novo* glomerulonephritis, and transplant renal artery stenosis have all been implicated in post-transplantation hypertension. In rare cases, excess renin output from the native kidneys has also been suggested to contribute to post-transplantation hypertension.⁴ In renal transplant recipients with severe hypertension refractory to medical therapy, bilateral native nephrectomy has been reported to improve blood pressure control.⁶

Management of post-transplantation hypertension should include attempts to identify and to treat the underlying etiology, lifestyle modifications (see Chapter 34), and treatment of associated CV risk factors. The initial target blood pressure goal is below 130/80 mm Hg, and in those with proteinuria, below 125/75 mm Hg. Although there is a lack of controlled clinical trials related to selection of antihypertensive agent, we recommend β -blockers in the perioperative setting as they have been shown to reduce ischemic heart disease events in high-risk candidates. In the early post-transplantation period, nondihydropyridine calcium channel blockers (CCBs) and diuretics are frequently used, the former for their beneficial effect on intraglomerular hemodynamics and the latter for their ability to eliminate salt and water in patients who are volume expanded postoperatively.

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) have been found to block calcineurin toxicity in experimental models and are protective in patients with CKD. Although these effects are desirable, they can cause acute changes in renal function as well as hyperkalemia and hence are usually not started until renal function is stable. A meta-analysis of 21 randomized controlled trials ($N = 1549$ patients) demonstrated that ACE inhibitors and ARBs reduce proteinuria in transplant recipients, but they also reduce hematocrit (-3.5% ; 95% CI -6.1 to -0.95) and glomerular filtration rate (GFR; -5.8 ml/min; 95% CI -10.6 to -0.99); there were insufficient data to determine a benefit on patient or graft survival.⁷ Serum potassium and creatinine concentrations must be closely monitored; a rising serum creatinine concentration of more than 30% above baseline should also prompt clinicians to consider transplant renal artery stenosis. Finally, dihydropyridine CCBs were once used extensively because they counter calcineurin vasoconstriction. However, an unexpected association has been reported between the use of dihydropyridine CCBs and an increased risk for ischemic heart disease.⁸ Dihydropyridine CCBs are also known to block renal autoregulation in CKD, in which they can increase proteinuria and may accelerate renal disease progression, especially in those not taking ACE inhibitors or ARBs.^{1-2,9,10} Dihydropyridine CCBs should therefore be

Cardiovascular Risk Factors in Transplant Recipients			
Conventional		Unconventional	
Modifiable	Nonmodifiable	Modifiable (+/- potentially modifiable)	Nonmodifiable
Hypertension	Family history	Anemia episodes	Prior acute rejection
Dyslipidemia	Diabetes mellitus	Proteinuria	Preexisting CAC
Obesity	Male gender	Hyperhomocysteinemia	Deceased vs. living donor
Smoking	Age	Inflammatory cytokines ↑ C-reactive protein CMV infection* Hyperuricemia Impaired allograft function† Left ventricular hypertrophy‡ CD4 lymphopenia§ Low albumin	Pretransplantation splenectomy

Figure 102.1 Cardiovascular risk factors in transplant recipients. *Strict adherence to cytomegalovirus (CMV) prophylaxis protocol/CMV surveillance in high-risk candidates. †Calcineurin inhibitor minimization or withdrawal at the discretion of the clinician (variable results/difficult-to-modify risk factor). ‡Optimize blood pressure control; use angiotensin-converting enzyme inhibitors, angiotensin receptor AT₁ blockers. §Assess risks and benefits of T cell-depleting antibody treatment. Further studies are needed. CAC, coronary artery calcification.

Potential Advantages and Disadvantages of Different Classes of Antihypertensive Agents ¹		
Classes of drugs	Advantages	Disadvantages
β-Blockers	Perioperative use ↓ ischemic heart disease events	↑ Risk of symptomatic bradycardia when used with nondihydropyridine CCB Blunting of hypoglycemic awareness
CCB	↓ CNI-induced renal vasoconstriction ² ↑ CNI level (may permit CNI dose reduction by up to 40%) ³	Monotherapy with dihydropyridine CCB should be used with caution ⁴
Diuretics	Beneficial in patients who are volume expanded postoperatively	Hyperuricemia, gout
ACE Inhibitor/ARB	↓ Proteinuria Potential renal protective and cardioprotective effects Beneficial in patients with post-transplantation erythrocytosis	Potential worsening of anemia
Aldosterone receptor Blockers	May improve outcomes in heart failure	Severe hyperkalemia when used in combination with ACEI/ARB or in patients with poor kidney function
α-2-Blockers	Benign prostatic hypertrophy Neurogenic bladder	
Direct vasodilators		Tachycardia
Central α agonist		Depression

Figure 102.2 Potential advantages and disadvantages of different classes of antihypertensive agents. ¹In general, there is no absolute contraindication to the use of any antihypertensive agent in renal transplant recipients. ²Both dihydropyridine and nondihydropyridine CCB. ³Nondihydropyridine CCB. ⁴See text. ACE inhibitor, angiotensin-converting enzyme inhibitors; ARB, angiotensin receptor blockers; CCB, calcium channel blockers; CNI, calcineurin inhibitors.

used as monotherapy with caution. Potential advantages and disadvantages of different classes of antihypertensive agents in renal transplant recipients are shown in Figure 102.2.

Post-transplantation Dyslipidemia

Dyslipidemia is common after transplantation, in part because of the hyperlipemic effect of corticosteroids, cyclosporine, tacrolimus, and sirolimus. Sirolimus and everolimus are associated with the worst lipid profiles, followed by cyclosporine and then tacrolimus. Other potential etiologic factors for post-transplantation

dyslipidemia include age, diet, rapid weight gain, hyperinsulinemia, preexisting hypercholesterolemia, allograft dysfunction, proteinuria, and the use of β-blockers and diuretics.

Although hyperlipidemia often improves within the first 6 months after transplantation as the doses of immunosuppressive agents are reduced, total and low-density lipoprotein cholesterol goals as defined by the National Cholesterol Education Program (NCEP) guidelines (<http://www.nhlbi.nih.gov/about/ncep/index.htm>) are usually not achieved. Most patients require statins, which are not only lipid lowering but also protective against CV

disease because of their additional effects of reducing circulating endothelin 1, C-reactive protein levels, systolic and diastolic blood pressure, and pulse pressure. However, the extent to which statins reduce C-reactive protein and ameliorate hemodynamic parameters remains to be studied.

The Assessment of Lescol in Renal Transplantation (ALERT) study demonstrated the efficacy of fluvastatin in reducing low-density lipoprotein cholesterol during a 5- to 6-year period. The incidence of major adverse cardiac events was also reduced with treatment, although this was not statistically significant. Additional analysis demonstrated a beneficial effect of early initiation of fluvastatin on CV outcome; patients who received statin therapy within the first 4 years after transplantation had a risk reduction of 64% compared with 19% for those who received therapy after 10 years. No statin effect on graft loss or doubling of serum creatinine was observed.^{11,12} In another study, there was better graft function at 12 months after transplantation in recipients who received statins compared with those who did not receive statin therapy (difference in creatinine clearance of 6 ml/min; $P < .001$); in addition, less interstitial fibrosis was seen on protocol biopsies.¹³

Whereas statins appear beneficial in transplant recipients, the use of statins in the presence of calcineurin inhibitors, particularly cyclosporine, often results in several-fold increases in statin blood level and an increased risk for myopathy and rhabdomyolysis.¹⁴

Other lipid-lowering agents include fibric acid derivatives, nicotinic acid, bile acid sequestrants, and ezetimibe. Ezetimibe and statin combination therapy can significantly improve cholesterol control because of their complementary mechanisms of action. Ezetimibe blocks intestinal absorption of dietary cholesterol and related phytosterols, whereas statin inhibits hepatic cholesterol synthesis. Ezetimibe used alone or as adjunctive therapy with statin appears safe and effective in the treatment of dyslipidemia in renal transplant patients who are refractory to statin therapy.¹⁵ In a single-center study, the addition of ezetimibe to statin therapy was shown to prevent the decline in renal function compared with controls.¹⁶ Whether ezetimibe and statin combination therapy is superior to statin-alone therapy in CV disease risk factor reduction remains to be elucidated. To date, no significant drug-drug interaction between ezetimibe and calcineurin inhibitors or sirolimus has been reported.

Drug Therapy for Hypertriglyceridemia and Non-High-Density Lipoprotein Cholesterol Severe hypertriglyceridemia (triglyceride level >500 mg/dl) is seen more frequently since the introduction of sirolimus. Management includes sirolimus dose reduction, addition of a fibric acid derivative or nicotinic acid, and, in refractory cases, switching of sirolimus to mycophenolate mofetil (MMF) or tacrolimus. Of the most used fibric acid medications—bezafibrate, ciprofibrate, fenofibrate, and gemfibrozil—the first three can increase serum creatinine in cyclosporine-treated patients. Although all fibrates in combination with statins have been associated with creatine kinase elevations with or without overt rhabdomyolysis and myopathy, gemfibrozil may have a greater risk for causing myopathy compared with bezafibrate or fenofibrate.¹⁴ Niacin monotherapy has not been reported to cause myopathy, but its combined use with lovastatin, pravastatin, or simvastatin may be associated with rhabdomyolysis. Bile acid sequestrants must be used with caution because of their potential interference with the absorption of other medications vital to renal transplant recipients. In addition, studies in the general population suggest that bile acid

sequestrants may increase triglyceride levels. For a more complete list of drug-drug interaction of statins with other lipid-lowering agents, readers are referred to reference 14.

The 2004 National Kidney Foundation Work Group suggested that statin therapy be the first-line treatment of non-high-density lipoprotein cholesterol because of its well-established safety and efficacy in preventing CV disease in randomized trials in the general population. Fibrates are used for those intolerant of statin despite dose reduction or despite switching to another statin. Randomized controlled trials evaluating the safety and efficacy of statins and fibrates are still needed. For patients with fasting triglyceride levels of 1000 mg/dl (11.29 mmol/l) or higher, the Adult Treatment Panel III (ATP III) recommends a very low fat diet ($<15\%$ total calories), medium-chain triglycerides, and fish oils to replace some long-chain triglycerides. Suggested guidelines for treatment of dyslipidemia are summarized in Figure 102.3.

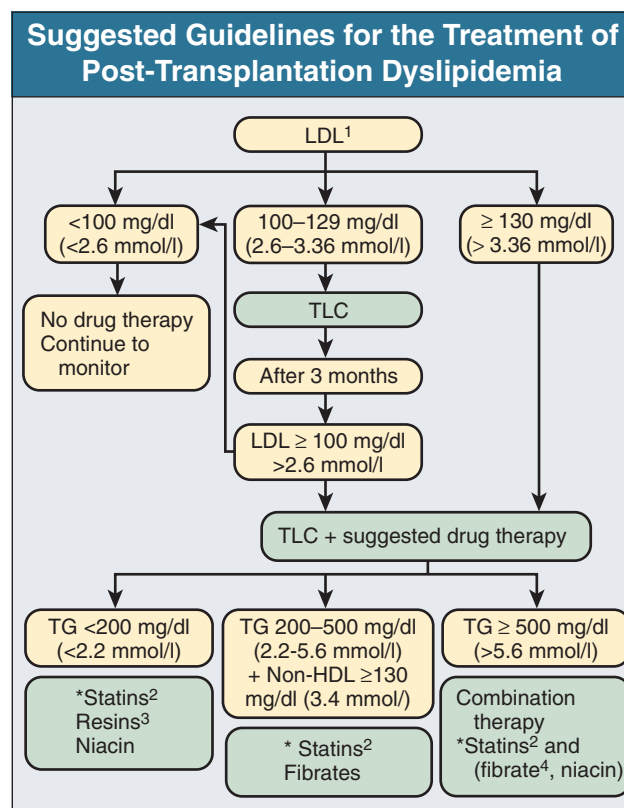

Figure 102.3 Suggested guidelines for the treatment of post-transplantation dyslipidemia. All transplant recipients should be regarded as coronary heart disease risk equivalent. Goals: low-density lipoprotein (LDL) <100 mg/dl (2.6 mmol/l) (optional <70 mg/dl) (1.8 mmol/l); triglyceride (TG) <200 mg/dl (2.2 mmol/l); high-density lipoprotein (HDL) >40 to 50 mg/dl (1.03–1.29 mmol/l).

*If LDL targets are not achieved with statin monotherapy, consider combination of statins plus cholesterol absorption inhibitors.⁵ TLC, therapeutic lifestyle change (see text).

¹LDL <70 mg/dl (1.8 mmol/l) has been suggested for very high risk patients (NCEP ATP III guidelines). ²Statins are the most effective drugs and should be the agents of first choice. Start at low dose in patients receiving cyclosporine and tacrolimus. Monitor for myositis and transaminitis, particularly in those receiving combination therapy. ³Bile acid sequestrants should probably not be taken at the same time as cyclosporine. ⁴Extreme caution should be used with statin and fibrate combination therapy. ⁵Consider cholesterol absorption inhibitors in patients intolerant of statins.

New-Onset Diabetes After Transplantation

New-onset diabetes after transplantation (NODAT) occurs in 4% to 25% of renal transplant recipients. The variation in reported incidence may be due to differences in definition, duration of follow-up, and the presence of both modifiable and non-modifiable risks factors. Major risk factors include African American and Hispanic ethnicity (compared with Caucasians or Asians), obesity defined as BMI of 30 kg/m² or higher, age older than 40 to 45 years, family history of diabetes among first-degree relatives, impaired glucose tolerance before transplantation or presence of other components of the metabolic syndrome, recipients of deceased donor kidneys, and hepatitis C infection. Risk factors among immunosuppressive therapies include corticosteroids and the calcineurin inhibitors tacrolimus and, to a lesser extent, cyclosporine¹⁶; neither azathioprine nor MMF is diabetogenic. MMF may even mitigate the diabetogenic effect of tacrolimus, possibly by allowing clinicians to use lower doses.

Sirolimus is now recognized to be associated with reduced insulin sensitivity and a defect in the compensatory β -cell response. Sirolimus may be diabetogenic by impairing insulin-mediated suppression of hepatic glucose production, causing ectopic triglyceride deposition leading to insulin resistance, and by direct β -cell toxicity.¹⁷

Other potential risk factors for the development of NODAT include the presence of certain HLA antigens (such as A30, B27, and B42), increasing HLA mismatches, acute rejection history, cytomegalovirus (CMV) infection, and male gender of recipient and donor.¹⁸ Polycystic kidney disease has been suggested to confer an increased risk for development of diabetes after renal transplantation in some studies but not in others.¹⁸ Risk factors for NODAT are summarized in Figure 102.4.

Management of NODAT Management of diabetes is similar to that of patients in the nontransplant setting, with a recommended target hemoglobin A_{1c} level below 6.5%. Fasting plasma glucose concentration should be below 100 mg/dl (6 mmol/l), and a 2-hour postprandial plasma glucose concentration should be below 140 mg/dl (7.8 mmol/l). Aggressive lowering of hemoglobin A_{1c} below 6.0% is not recommended because of risks of hypoglycemia and because in nontransplant patients this has been associated with increased mortality.¹⁹

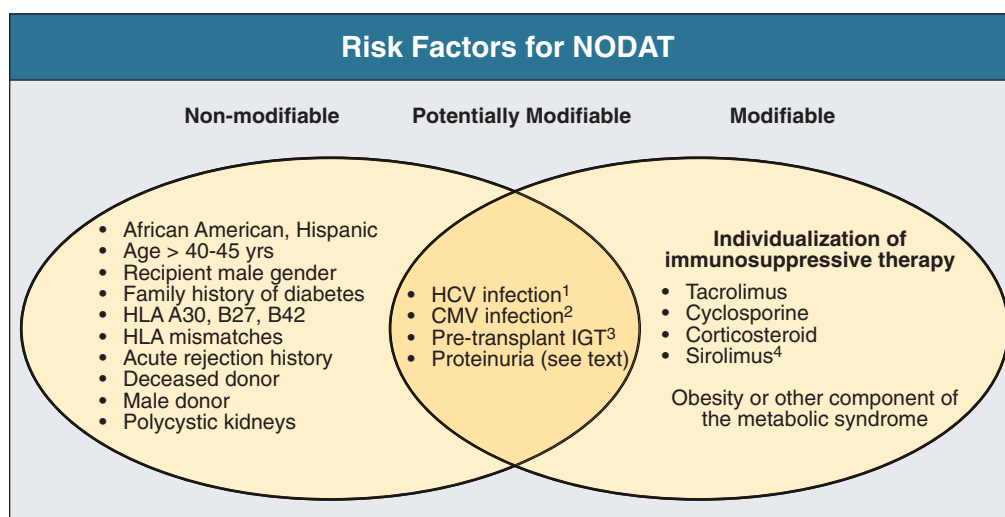

Overweight adults with impaired glucose tolerance should undergo lifestyle modifications including moderation of dietary sodium (<2400 mg of sodium a day) and saturated fat intake (<7% of calories from saturated fats, 2% to 3% of calories from *trans*-fatty acids), regular aerobic exercise, and weight reduction. Carbohydrate intake should be limited to 50% to 60% of calorie intake. The American Heart Association guidelines also suggested more than 25 g/day of dietary fiber and two servings of fish per week. Defining realistic goals, such as a target weight loss of 5% to 10% of total body weight, and a patient-centered approach to education may be invaluable in achieving success.

Modification of immunosuppression should be considered in high-risk patients. Corticosteroid dose reduction significantly improves glucose tolerance during the first year after transplantation. However, any dose reduction should be weighed against the risk of acute rejection. Conversion of tacrolimus to cyclosporine in patients who fail to achieve target glycemic control has yielded variable results.

Orally administered agents can be used either alone or in combination with insulin. Although oral agents are often effective, insulin therapy may be necessary in up to 40% of patients, particularly in the early post-transplantation period. The choice of pharmacologic therapy is based on the potential advantages and disadvantages associated with the different classes of oral agents. Metformin (*a biguanide derivative*) is preferred for overweight patients but is contraindicated in patients with impaired graft function (GFR <60 to 70 ml/min) as in this setting it can cause lactic acidosis. *Sulfonylurea derivatives* must be prescribed with care to patients with impaired graft function or to elderly patients because of the increased risk of hypoglycemia. In these patients, it is best to start with a low dose and to titrate upward every 1 to 2 weeks. The “non-sulfonylurea” *meglitinides* are insulin secretagogues with a mechanism of action similar to that of the sulfonylureas. They have a more rapid onset and shorter duration of action and seemingly lower risks of hypoglycemia. These agents are best suited for patients whose food intake is erratic, elderly patients, and patients with impaired graft function. They are best taken before meals, and the dose may be omitted if a meal is missed.

The *thiazolidinedione derivatives* (TZDs) are insulin sensitizers that may allow a reduction in insulin requirement. Potential adverse effects of these agents include weight gain, peripheral

Figure 102.4 Risk factors for new-onset diabetes after transplantation (NODAT). ¹Consider pretransplantation treatment of HCV (see text). ²Aggressive post-transplantation CMV prophylaxis. ³Counseling on lifestyle modifications. ⁴Further studies are needed. HLA, human leukocyte antigen; HCV, hepatitis C virus; CMV, cytomegalovirus; IGT, impaired glucose tolerance.

edema, anemia, pulmonary edema, and congestive heart failure. The incidence of peripheral edema is increased when TZDs are used in combination with insulin. More recently, during the A Diabetes Outcome Progression Trial (ADOPT) conducted to compare glycemic control in patients taking rosiglitazone, metformin, or glyburide, a higher incidence of fractures on the upper arm, hand, and foot among female patients treated with rosiglitazone was noted.^{20,21} Subsequently, pioglitazone was also recognized to have similar increased risks of fractures in women but not in men, although further studies are needed.²¹ The risk of fractures associated with the use of TZDs in the transplant setting is currently not known. Nonetheless, TZDs should be used with caution, particularly in female transplant recipients who are also receiving corticosteroids.

The incretin mimetics *glucagon-like peptide 1 analogues* (GLP-1) and incretin enhancers *dipeptidyl peptidase 4 inhibitors* (DPP-4) belong to a novel class of drugs that have been approved for use in type 2 diabetes. In contrast to insulin and most other glucose-lowering agents that cause weight gain and hypoglycemia, GLP-1 inhibitors and DPP-4 inhibitors have either a favorable or neutral effect on weight reduction and a lower risk of hypoglycemia. Exenatide is an incretin mimetic that stimulates insulin biosynthesis and secretion in a glucose-dependent manner and has been shown to lower both fasting and postprandial glucose concentrations. When it is added to sulfonylureas, thiazolidinediones, or metformin, it results in additional lowering of hemoglobin A_{1c} by approximately 0.5% to 1%. It also promotes weight loss through its effects on satiety and delayed gastric emptying. Sitagliptin and vildagliptin are DPP-4 inhibitors that act by enhancing the sensitivity of β cells to glucose, thereby enhancing glucose-dependent insulin secretion; they have also been shown to improve markers of β -cell function. Overall, this class of drugs has been shown to have neutral effects on weight.

Incretin-based therapy is an attractive treatment option for patients with NODAT because of its favorable effect on weight reduction/neutrality. Data on its safety and efficacy in renal transplant recipients are currently lacking. Caution should be exercised when these agents are used in the transplant setting, particularly with regard to drug-drug interactions. Vildagliptin should be avoided in patients with hepatic impairment, and the dose of sitagliptin should be adjusted for renal insufficiency.

The routine care of patients with post-transplantation diabetes mellitus should include an evaluation of hemoglobin A_{1c} level every 3 months and regular screening for diabetic complications, including microalbuminuria, retinopathy, and polyneuropathy with associated lower extremity ulcerations and infections. Fasting lipid profile should be measured annually. In transplant recipients with multiple CV risk factors, more frequent monitoring of lipid profile should be performed at the discretion of the clinicians. Figure 102.5 summarizes the suggested guidelines for the management of NODAT. Of note, hemoglobin A_{1c} cannot be accurately interpreted within the first 3 months after transplantation as anemia and impaired renal function can directly interfere with the A_{1c} assay. Recent blood transfusions or the use of dapsone may also alter hemoglobin A_{1c} levels.

Cigarette Smoking

As in the general population, cigarette smoking is associated with increased CV morbidity and mortality in renal transplant recipients.^{22,23} Stopping smoking 5 years before transplantation reduced the risk of death by 29% (RR, 0.71; $P = .0304$).²³ Every effort should be made to encourage patients to stop smoking. A

Management of New-Onset Diabetes Mellitus After Transplantation

Dietary modification

Dietitian referral

For diabetic dyslipidemia: a diet low in saturated fats and cholesterol and high in complex carbohydrates and fiber is recommended.

The AHA¹ guidelines suggest limiting cholesterol (<200 mg/day for those with diabetes mellitus); $\leq 7\%$ of calories from saturated fats, 2% to 3% of calories from trans-fatty acids, and ≤ 2400 mg sodium/day. More than 25 g/day of dietary fiber and 2 servings of fish a week are also recommended.

Lifestyle modifications

Exercise

Weight reduction or avoidance of excessive weight gain

Smoking cessation

Adjustment or modification in immunosuppressive medications²

Rapid steroid taper, steroid-sparing or steroid avoidance protocols

Tacrolimus to cyclosporine conversion

Pharmacologic therapy

Acute, marked hyperglycemia (may require inpatient management)

Intensive insulin therapy (consider insulin drip when glucose ≥ 400 mg/dl)

Chronic hyperglycemia: treat to target Hb A_{1c} $\geq 6.5\%$

Oral glucose-lowering agent monotherapy or combination therapy³ and/or insulin therapy

Consider diabetologist referral if Hb A_{1c} remains $\geq 9.0\%$

Monitoring of patients with NODAT

Hemoglobin A_{1c} every 3 months

Screening for microalbuminuria

Regular ophthalmologic examination

Regular foot care

Annual fasting lipid profile

Aggressive treatment of dyslipidemia and hypertension

Figure 102.5 Management of new-onset diabetes mellitus after transplantation. ¹American Heart Association. ²Clinicians must be familiar with the patient's immune history before manipulating immunosuppressive therapy. ³The choice of a particular agent should be based on the characteristics of each individual patient (see text). (Modified from reference 1.)

multifaceted approach including behavioral and pharmacologic strategies appears to be most effective.

Obesity

Obesity has a reported prevalence of 9.5% to 29% in transplant recipients. Studies in renal transplant recipients have shown that high BMI at transplantation is a significant independent predictor of congestive heart failure and atrial fibrillation.^{24,25} The impact of BMI on cardiac-related death follows a U-shaped risk. In a large registry study, the adjusted risk of cardiac death increased at both low and high BMI compared with a reference group with a BMI of 22 to 24 (relative risk of 1.3 for BMI <20 and 1.4 for BMI >36).²⁶

Management of post-transplantation obesity includes lifestyle and dietary modifications. Corticosteroid reduction or withdrawal must be balanced against the risk of graft rejection and graft loss. The use of pharmacologic agents for weight reduction in the post-transplantation period is currently not recommended because of unknown potential drug-drug interactions. There is a paucity of data on the safety and efficacy of post-transplantation gastric bypass surgery in ameliorating comorbid conditions such as hypertension, diabetes mellitus, and dyslipidemia. In a recent analysis of the U.S. Renal Data System (USRDS) database, mortality rates in patients undergoing gastric bypass after transplantation were higher compared with those without kidney disease who had undergone the same surgery. Although the difference in mortality rates was thought to be within “acceptable range” and attributed to poor healing associated with the use of immunosuppressive therapy, the routine recommendation of post-transplantation bariatric surgery awaits further studies.²⁷

Unconventional Cardiovascular Disease Risk Factors

Proteinuria

Proteinuria has been reported in 9% to 40% of kidney transplant recipients with a functioning graft.¹ Controlled trials evaluating the beneficial effect of treating proteinuria in reducing CV risk in renal transplant recipients are lacking. Nonetheless, unless it is contraindicated, ACE inhibitors or ARBs should be considered in transplant recipients with microalbuminuria or overt proteinuria because of their well-established renoprotective, antiproteinuric, and cardioprotective effects. Whether the development of proteinuria associated with sirolimus adversely affects CV risks is currently unknown.

COMMON LABORATORY ABNORMALITIES

Anemia

Mild anemia is common in the early post-transplantation period when erythropoietin therapy is typically discontinued, but it generally improves within several weeks to months. Suggested etiologic factors for post-transplantation anemia include iron deficiency, folate deficiency, vitamin B₁₂ deficiency, impaired graft function, acute rejection episodes, recent infection, and medications (such as azathioprine, MMF, sirolimus, and ACE inhibitors and ARBs). Anemia has also been reported to be more common in African American and female transplant recipients.

Profound iron deficiency should be treated with intravenous iron as tolerated. Erythropoietin and darbepoetin alfa are effective in the treatment of anemic renal transplant recipients. Refractory or severe anemia mandates a search for postoperative bleeding, particularly in those with a rapid fall in hematocrit. Other possibilities include tertiary hyperparathyroidism, underlying inflammatory conditions, and parvovirus B19 infection.

Erythropoietin-resistant anemia has been described in patients receiving sirolimus immunosuppression. In stable kidney transplant recipients, conversion from sirolimus to enteric-coated MMF may help resolve anemia in these patients.²⁸

Leukopenia and Thrombocytopenia

Leukopenia and thrombocytopenia may be the result of myelosuppression due to medications including azathioprine, MMF,

antilymphocyte antibody treatment, sirolimus, and trimethoprim-sulfamethoxazole. Withholding of the offending agent or dose reduction generally corrects these hematologic abnormalities. Severe leukopenia may be safely treated with granulocyte-stimulating factor. Thrombotic microangiopathy or CMV infection should be excluded. Parvovirus B19 infection may present with refractory anemia, pancytopenia, and thrombotic microangiopathy. More recently, an increase in the incidence of leukopenia was found in kidney and pancreas transplant recipients receiving alemtuzumab induction therapy.

Erythrocytosis

Post-transplantation erythrocytosis (PTE) occurs in 20% to 25% of transplant recipients within the first 2 years. Risk factors for PTE include the presence of native kidneys, male gender, excellent graft function and the absence of rejection episodes, high baseline hemoglobin concentration before transplantation, smoking, hypertension, and diabetes mellitus. Transplant renal artery stenosis is a risk factor for PTE in some but not all studies. Suggested pathogenic mechanisms include defective feedback regulation of erythropoietin metabolism, direct stimulation of erythroid precursors by angiotensin II, and abnormalities in circulating insulin-like growth factor 1 levels. Serum erythropoietin levels are inconsistently elevated.

Treatment is recommended for hemoglobin levels of 17 to 18 g/dl and higher or hematocrit levels of 52% to 55% and higher because of the associated risk of thromboembolic complications, hypertension, and headaches. Treatment with ACE inhibitors or ARBs is often sufficient, although phlebotomy may occasionally be necessary. A negative association between the use of sirolimus and PTE has been reported.²⁹ Whether sirolimus might prove to be beneficial in the prevention and treatment of PTE remains to be studied.

Hyperkalemia

Mild hyperkalemia is common in renal transplant recipients, particularly in the early post-transplantation period when relatively high doses of calcineurin inhibitor are given. It is often associated with mild hyperchloremic acidosis, a clinical presentation reminiscent of type 4 renal tubular acidosis. Suggested mechanisms of calcineurin inhibitor-induced hyperkalemia include hyporeninemic hypoaldosteronism, aldosterone resistance, and inhibition of cortical collecting duct potassium secretory channels. Cyclosporine decreases Na⁺,K⁺-ATPase activity in potassium secretory cells in the cortical and outer medullary collecting tubules, thereby decreasing intracellular potassium accumulation required for urinary secretion. In patients receiving cyclosporine or tacrolimus, a serum potassium level in the range of 5.2 to 5.5 mmol/l is typically seen and generally does not require treatment. Higher potassium levels, especially in the presence of concomitant use of drugs that may exacerbate hyperkalemia, such as ACE inhibitors, ARBs, and β -blockers, may require their discontinuation. Caution is needed when potassium-containing phosphorus supplements are prescribed. Although trimethoprim can cause hyperkalemia through an amiloride-like effect, the routine use of low-dose trimethoprim-sulfamethoxazole for prophylaxis is rarely the cause of severe or refractory hyperkalemia in renal transplant recipients. Finally, because efficient renal potassium secretion requires good urine flow, urinary obstruction must also be considered in the presence of hyperkalemia.

Treatment of hyperkalemia is discussed in Chapter 9. Sodium polystyrene sulfonate (Kayexalate) or calcium resonium enemas should be avoided in the immediate post-transplantation period to avoid colonic dilation and perforation.

Hypokalemia

Sirolimus may be associated with hypokalemia. Hypokalemia has been reported in 34% and potassium supplementation was required in 27% of patients treated with sirolimus.³⁰ Sirolimus-induced increased tubular secretion of potassium has been suggested as a possible mechanism.³¹

Hypophosphatemia

Hypophosphatemia is frequently encountered in the first months after transplantation, and when it is associated with hypercalcemia, it suggests post-transplantation hyperparathyroidism. In the absence of hypercalcemia, renal phosphate wasting syndrome or malnutrition should be considered.

Early after transplantation, hypophosphatemia may also be due to massive initial diuresis (particularly after living donor renal transplantation, when there is immediate graft function), defective renal phosphate reabsorption due to ischemic injury, glucosuria (due to hyperglycemia-induced osmotic diuresis), magnesium depletion, and corticosteroid use—the last by inhibiting proximal tubular reabsorption of phosphate. More recently, persistent increases in fibroblast growth factor 23 (FGF-23, a phosphatonin) in the post-transplantation period have been suggested to contribute to persistent hypophosphatemia.³² FGF-23 enhances phosphate clearance and is elevated in CKD.

Treatment of hypophosphatemia is discussed in Chapter 10.

Hypercalcemia

Hypercalcemia is common after transplantation and is generally due to persistent secondary hyperparathyroidism. The concomitant presence of severe hypophosphatemia, particularly in patients with excellent graft function, may exacerbate hypercalcemia through stimulation of renal proximal tubular 1α -hydroxylase. Resolution of soft tissue calcifications, high-dose corticosteroid therapy, and immobilization are potential contributing factors. In about two thirds of cases, hypercalcemia resolves spontaneously within 6 to 12 months. However, spontaneous resolution occurs in less than half of those whose hypercalcemia existed before transplantation. Persistent hyperparathyroidism has generally been attributed to continued autonomous production of parathyroid hormone from nodular hyperplastic glands, reduced density of calcitriol receptors, and decreased expression of the membrane calcium sensor receptors that render cells more resistant to physiologic concentrations of calcitriol and calcium. The risk for development of persistent hyperparathyroidism is increased with the duration of dialysis and the severity of pretransplantation hyperparathyroidism. Severe hypercalcemia (>11.5 mg/dl [2.9 mmol/l]) or persistent hypercalcemia (≥ 12 months) requires further evaluation. Initial assessment should include an intact parathyroid hormone level. Imaging studies, including neck ultrasound or parathyroid technetium Tc 99m sestamibi scan, are required to determine if the clinically observed hyperparathyroidism arises from parathyroid adenoma, parathyroid gland hyperplasia, or hyperplastic nodular formation of the parathyroid glands.

Cinacalcet has been shown to reduce serum calcium in renal transplant recipients with hypercalcemic hyperparathyroidism. Parathyroidectomy is warranted in patients with tertiary hyperparathyroidism or persistent severe hypercalcemia for more than 6 to 12 months, symptomatic or progressive hypercalcemia, nephrolithiasis, persistent metabolic bone disease, calcium-related renal allograft dysfunction, or progressive vascular calcification and calciphylaxis.³³ Whether the advent of calcimimetics will reduce the need for parathyroidectomy remains to be studied.

Hypomagnesemia

Cyclosporine, tacrolimus, and sirolimus cause hypomagnesemia by inducing urinary magnesium wasting. Other factors that may contribute to post-transplantation hypomagnesemia include recovery from acute tubular necrosis, postobstructive polyuria, loop diuretic therapy, and renal tubular acidosis. Hypomagnesemia may be more common in diabetics. Serum magnesium concentration below 1.5 mg/dl (0.62 mmol/l) is common. Dietary magnesium intake is usually insufficient, and high-dose oral magnesium supplementation (e.g., 400 to 800 mg magnesium oxide three times a day) may be required. The intravenous administration of magnesium should be considered with severe hypomagnesemia (<1.0 mg/dl [0.41 mmol/l]), particularly in patients with coronary artery disease, in those with cardiac arrhythmias, and in those taking digitalis. Aggressive treatment of hypomagnesemia reduces cyclosporine-induced neurotoxicity and aids blood pressure control.

Abnormal Liver Function Test Results

Elevation of hepatic enzymes is common in the early post-transplantation period and is generally due to drug-related toxicity. Potential culprits include acyclovir, ganciclovir, trimethoprim-sulfamethoxazole, cyclosporine, tacrolimus, statins, and proton pump inhibitors. Cyclosporine and, less commonly, tacrolimus may cause transient, self-limited, dose-dependent elevations of transaminases and mild hyperbilirubinemia secondary to defective bile secretion. Elevated liver enzymes due to drug-related adverse effect usually improve or resolve after drug discontinuation or dose reduction.

Persistent or profound elevation in hepatic liver enzymes should prompt further evaluation to exclude infectious causes, including CMV, hepatitis B virus (HBV), and hepatitis C virus (HCV). In high-risk candidates for primary CMV infections (recipient seronegative, donor seropositive), it may occasionally be necessary to initiate CMV therapy pending laboratory results, particularly when there is a high index of clinical suspicion (fever, fatigue, malaise, gastroenteritis, leukopenia, or thrombocytopenia). Evidence of post-transplantation HBV reactivation (elevated alanine transaminase, histologic hepatitis, and serum DNA $>10^5$ copies/ml) should be treated with lamivudine. Some centers routinely initiate lamivudine prophylaxis in all HBsAg-positive candidates at the time of transplantation. Pretransplantation lamivudine prophylactic therapy is recommended in renal transplant candidates who have HBV DNA above 10^5 copies/ml and active liver disease, defined as an alanine transaminase value more than two times the upper limit of normal or biopsy-proven hepatic disease. Newer nucleoside analogs including entecavir and tenofovir have been recently recognized to provide improved viral suppression with lower emergence of resistance and toxicity and have become preferred first-line treatment options for patients with chronic hepatitis B. However, renal

Algorithm for the Management of Elevated Hepatic Enzymes in Renal Transplant Recipients

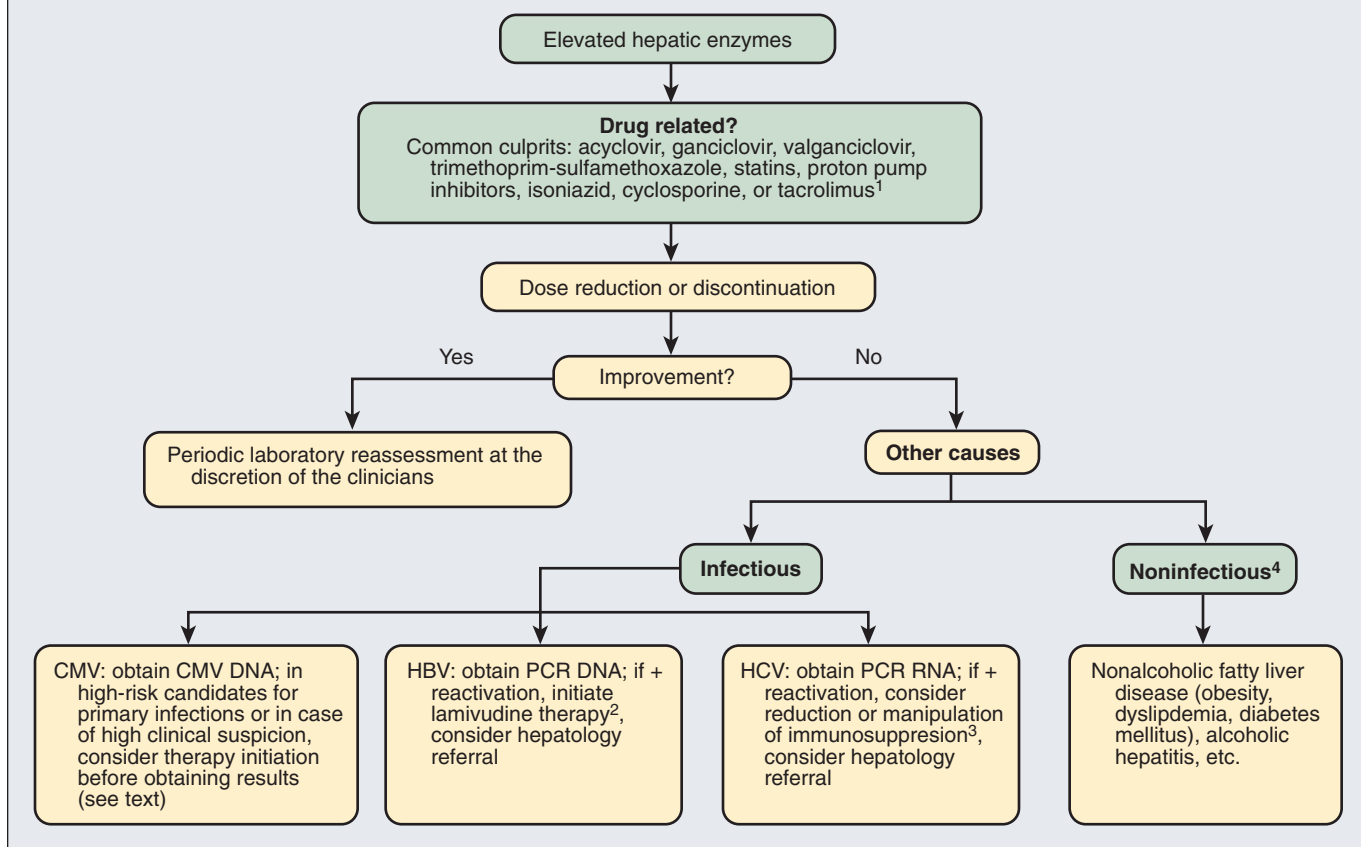

Figure 102.6 Algorithm for the management of elevated hepatic enzymes in renal transplant recipients. ¹Cyclosporine and less commonly tacrolimus may cause transient, self-limited, dose-dependent elevations of aminotransferase levels and mild hyperbilirubinemia secondary to defective bile secretion. ²Some programs routinely commence lamivudine prophylactic therapy in all HBsAg-positive candidates at the time of transplantation. ³There is currently no effective treatment of chronic hepatitis C in renal transplant recipients (see text). ⁴Appropriate evaluation and management similar to nontransplant settings. CMV, cytomegalovirus; HBV, hepatitis B virus; HCV, hepatitis C virus; PCR, polymerase chain reaction.

dose adjustments and close monitoring of renal function with the use of tenofovir are advised due to its nephrotoxic potential.

There is currently no effective treatment of chronic hepatitis C in renal transplant recipients. Although treatment with interferon alpha may result in clearance of HCV RNA in 25% to 50% of cases, rapid relapse after drug withdrawal is nearly universal. More important, interferon alpha treatment has been shown to precipitate acute graft rejection and graft loss and is currently not recommended for renal transplant recipients with HCV infection. Management of HCV infection in this population of patients should probably rely on manipulation of immunosuppressive therapy. Experiences gained from liver transplantation indicate that corticosteroid therapy and antilymphocyte antibody treatment are associated with enhanced viral replication and more rapid progression to cirrhosis. On the basis of these observations, it is advisable to avoid antilymphocyte antibody induction therapy and to minimize corticosteroid dosage in transplant recipients with chronic HCV infection. Although early reports suggested that MMF may reduce HCV replication and delay recurrence in hepatitis C–positive liver transplant recipients, the antiviral properties of MMF and its impact on HCV replication and hepatitis C recurrence have not been consistently demonstrated in subsequent studies.

In vitro studies show that cyclosporine and mycophenolic acid (the active metabolite of MMF) are an effective combination for inhibition of HCV replication in the presence of interferon. In contrast, tacrolimus and methylprednisolone reduce rather than enhance the efficacy of interferon.³⁴ HCV-associated chronic hepatitis occurs in a significantly smaller number of patients treated with cyclosporine rather than tacrolimus. These studies suggest that cyclosporine may be superior to tacrolimus as an immunosuppressive agent in HCV-infected renal transplant recipients. An algorithm for the management of renal transplant recipients with elevated hepatic enzymes is shown in Figure 102.6.

BONE AND MINERAL METABOLISM AFTER TRANSPLANTATION

Post-transplantation Bone Disease

Post-transplantation bone disease is a common complication after kidney transplantation due to persistent renal osteodystrophy, the adverse effects of immunosuppression (mainly corticosteroids), persistent hyperparathyroidism, abnormalities in vitamin D metabolism, and reduced GFR. Corticosteroids

directly inhibit osteoblastogenesis and induce apoptosis of osteoblasts and osteocytes. Corticosteroids also inhibit intestinal calcium absorption, enhance renal calcium excretion, and directly suppress gonadal hormone secretion. Low 25-hydroxyvitamin D levels after renal transplantation may also contribute to bone disease.

Other factors that have been suggested to contribute to post-transplantation bone loss include “normal” age-dependent osteoporosis, persistent metabolic acidosis, phosphate depletion, diabetes mellitus, hypogonadism, and smoking. Animal models suggest that cyclosporine and tacrolimus may also contribute to post-transplantation bone loss by stimulating bone resorption. The effects of calcineurin inhibitors in humans remains speculative, although increasing alkaline phosphatase and osteocalcin and increased osteoblastic and osteoclastic activities have been reported with cyclosporine treatment compared with azathioprine.

Osteoporosis

Post-transplantation decline in bone mineral density (BMD) is most pronounced in the first 6 months and correlates with higher corticosteroid exposure in the early post-transplantation period. The rate of bone loss varies from 3% to 10% and is most apparent at sites of cancellous bone, particularly the lumbar spine and axial skeleton. This early rapid decrease in BMD is usually followed by a slower rate of bone loss and reflects cumulative corticosteroid dose. Nonetheless, controversies exist as to whether bone loss continues to decline, stabilizes, or even reverses after the first year. A decrease in BMD averaging 1.7% per year in later post-transplantation years has been reported, whereas stabilization during the second year followed by an improvement of 1% to 2% per year thereafter was observed by others. Nevertheless, osteopenia and osteoporosis prevalence ranges from 31% to 41% 20 years after renal transplantation.

Evaluation of patients for bone loss or osteoporosis relies on the measurement of BMD by dual-energy x-ray absorptiometry (DEXA) scan. However, in the setting of combined osteoporosis and CKD, DEXA may be completely misleading. For instance, adynamic bone disease, mild hyperparathyroidism, and genuine osteoporosis may yield the same BMD, yet therapy is very different. Hence, BMD can only be interpreted in the clinical and laboratory setting, and bone biopsy should be performed if uncertainty arises.

Avascular Necrosis

Post-transplantation osteonecrosis (avascular necrosis) occurs with an incidence of 3% to 16% and most commonly affects the femoral head and neck. It usually occurs within the first few years after transplantation and may affect other joints, including the knees, shoulders, and, less commonly, ankles, elbows, and wrists. Early avascular necrosis of the femoral head commonly presents with hip or groin pain or referred knee pain. Symptoms may be aggravated by weight bearing but may also be paradoxically worse at night. Use of crutches to avoid weight bearing on the affected side is advisable. Core decompression, with or without bone grafting before the femoral head collapse, may relieve pain, but approximately 60% of cases require total arthroplasty. Osteotomy has also been used as a joint-sparing technique to treat osteonecrosis. Core decompression and osteotomy may have similar efficacy in early disease, but intertrochanteric osteotomy may be preferred for patients who have progressed to collapse of the femoral head by the time of diagnosis. Drastic corticosteroid dose reduction or discontinuation has little if any effect on

altering the course of established avascular necrosis and may jeopardize graft function. Magnetic resonance imaging is the most sensitive technique for early detection; plain radiographs are of limited diagnostic value in the early stage. Predisposing factors for the development of avascular necrosis include greater exposure to intravenous corticosteroid pulse therapy, low bone mass, hyperparathyroidism, increasing dialysis duration, excessive weight gain, hyperlipidemia, microvascular thrombosis, and history of local trauma. Studies in renal transplant recipients maintained on a corticosteroid-free immunosuppressive regimen demonstrated low rates of avascular necrosis at 3-year follow-up.³⁵

Prevention and Management of Post-transplantation Bone Disease

Management of post-transplantation bone disease has largely been based on studies involving postmenopausal osteoporosis and corticosteroid-induced osteopenia in nontransplant settings. Adequate calcium and vitamin D supplementation is generally recommended after transplantation to prevent rapid bone loss in the first post-transplantation year. Serum 25-hydroxyvitamin D levels should be obtained and levels kept above 30 ng/ml. In patients at increased risk for fracture, consideration should be given to rapid corticosteroid withdrawal or corticosteroid-free immunosuppressive protocols after the risks and benefits of acute rejection are weighed.

Bisphosphonates increase BMD in postmenopausal women and patients with corticosteroid-induced osteoporosis, particularly at the lumbar spine and trochanter. Although most studies to date suggest that bisphosphonates have a greater effect on increasing BMD than vitamin D analogues do, their efficacy in terms of fracture reduction compared with vitamin D analogues remains to be determined. In addition, because of the potential for bisphosphonates to oversuppress bone metabolism, their use in kidney transplant recipients with known adynamic bone disease remains unclear. Nonetheless, bisphosphonate therapy may be justifiable in potential high-risk candidates, including those with preexisting fractures or severe osteoporosis, patients with diabetes mellitus, postmenopausal women, and recipients of simultaneous pancreas-kidney transplants. The Kidney Disease: Improving Global Outcomes (KDIGO) guidelines suggest that consideration be given to bone biopsy before bisphosphonate therapy.

Other treatments are problematic. Calcitonin is considered relatively ineffective. Many older women and women with CKD also have deficiency in estrogen, and limited studies have shown that estrogen replacement therapy improves BMD in postmenopausal liver, lung, and bone marrow transplant recipients. Nonetheless, the CV risk associated with estrogen use may outweigh its benefits, and estrogen should be used with caution. Testosterone deficiency has also been implicated in the development of bone loss and fractures after transplantation. However, because testosterone may cause dyslipidemia, hepatic enzyme abnormalities, erythrocytosis, and prostatic hypertrophy, testosterone should probably be given only to men with true hypogonadism.

Gout

Hyperuricemia and gout are common among renal transplant recipients receiving cyclosporine-based immunosuppression, with a reported prevalence of 30% to 84% and 2% to 28%, respectively. Cyclosporine impairs renal excretion of uric acid secondary to decreases in GFR and increases net uric acid

reabsorption by the proximal tubule. Potential contributing risk factors for the development of post-transplantation hyperuricemia and gouty arthritis include pretransplantation hyperuricemia, impaired graft function, obesity, and diuretic use.

Management of the acute gouty attack includes topical ice and rest of the inflamed joint. Pharmacologic treatments include colchicine, increased corticosteroid dose, and nonsteroidal anti-inflammatory agents (NSAIDs). The use of NSAIDs, however, should be avoided in patients with impaired graft function. Other treatment options have included intra-articular corticosteroids and parenteral adrenocorticotrophic hormone (ACTH); ACTH is reserved for patients with multiple medical problems, such as impaired graft function, gastrointestinal bleeding, or gouty arthritis refractory to conventional therapy.

Management of chronic gout is directed at lowering of uric acid levels. Allopurinol should be started at a low dose (100 to 200 mg/day), particularly in the presence of impaired allograft function, because renal insufficiency predisposes to severe allopurinol toxicity due to retention of the metabolite oxypurinol. Allopurinol and azathioprine combination therapy should be avoided because of inhibition of azathioprine metabolism by allopurinol. In allopurinol-allergic patients, the new xanthine oxidase inhibitor febuxostat can be used. It is administered as 40 or 80 mg daily, and the dosing is not modified in renal failure.

Long-term prophylaxis may include reduction or discontinuation of diuretics, chronic low-dose allopurinol therapy, dietary modification, and consideration of alternative immunosuppressive therapy. Cyclosporine to tacrolimus switch has been reported to result in resolution of severe polyarticular gout refractory to conventional therapy. Small doses of colchicine at 0.6 mg daily may also prevent recurrent gouty attacks. However, colchicine should be used with caution, particularly in patients on statin therapy, due to the increased risk of myopathy. NSAIDs should be avoided in patients with impaired graft function.

OUTPATIENT CARE

We recommend that patients be seen two or three times a week for the first 2 weeks after transplantation, twice a week for the next 2 weeks, and weekly for the next month. After the first 2 months, the frequency of outpatient visits depends on the complexity of the patient's early postoperative course. Patients with stable graft function and an uneventful postoperative course can return to work or their regular daily activities 2 to 3 months after transplantation. Laboratory assessment during the first month after transplantation should include serum creatinine concentration and electrolyte values, fasting glucose level, liver enzymes, calcium and phosphorus levels, immunosuppressive drug levels, and complete blood count with platelets. Urine dipstick (and, if clinically indicated, urine culture and urine protein/creatinine ratio to monitor for disease recurrence, such as focal segmental glomerulosclerosis) should also be performed. After the first post-transplantation month, pertinent laboratory evaluation should be performed at the discretion of the clinician. After the first post-transplantation year, annual follow-up at a transplantation center is generally recommended.

Chronic Allograft Injury

Moses D. Wavamunno, Philip J. O'Connell

DEFINITIONS

Advances in immunosuppression have resulted in a continuing reduction in acute rejection rates and improvement in short-term graft survival. However, this short-term improvement has had surprisingly little impact on long-term graft survival.¹ In the last 2 decades, 1-year renal allograft survival has increased from 50% to 94% in deceased donor kidney transplants and up to 97% in living related transplants. However, late graft loss continues to be the “Achilles’ heel” of renal transplantation, with 5- and 10-year survival rates reported as 91% and 58% for deceased donor transplants and 90% and 77% for living donor recipients from U.S. registry data.² Australia and New Zealand registry data (ANZDATA) show that between 1991 and 1997, 1-year primary deceased donor graft survival improved from 85% to 91%, with only modest improvements in 5-year survival.³

A large proportion of late graft loss is preceded by chronic transplant dysfunction, a clinicopathologic syndrome characterized by slow progressive decline in graft function, proteinuria, hypertension, and histopathologic features of interstitial fibrosis and tubular atrophy. This was initially referred to as *chronic rejection*, a concept that emerged in the 1950s when arterial intimal fibrosis and glomerular abnormalities were seen in transplant recipients with late acute rejection episodes and circulating alloantibody,⁴ and then severe recurrent rejection and late cellular rejection were noted as independent risk factors for graft failure.⁵ For many years, it was believed that late allograft dysfunction was solely the result of an immune-mediated process.

The term *chronic allograft nephropathy*, introduced in 1991, was used to describe the same pathologic features as it had become increasingly clear that they are due to multiple different causes, of which the alloimmune response is but one.⁶ More recently, there has been concern that chronic allograft nephropathy has been inappropriately considered a specific disease state rather than a term for nonspecific scarring. It was thought that the term inhibited the search for an accurate etiologic diagnosis, and hence it has been eliminated from the Banff classification of renal allograft pathology.⁷ In recent years, there has been renewed emphasis on the importance of developing more specific etiologic diagnoses, such as chronic antibody-mediated rejection. However, this still leaves a large number of biopsies in which the injury is either multifactorial or unknown. This is now described in the Banff schema as *interstitial fibrosis/tubular atrophy with no evidence of specific etiology (IF/TA)* as a more specific description of the pathologic features. The new Banff schema is shown in Figure 103.1.

The problem with these terms is that they group together all causes rather than take into account the many factors important

in the pathogenesis of the condition. These are discussed later but include, for example, prior donor disease, alloimmune factors, calcineurin inhibitor (CNI) nephrotoxicity, BK virus nephropathy, chronic hypertension, obstructive uropathy, and recurrent disease. In any individual patient, some or all of these features may play a role in the development of IF/TA and chronic transplant dysfunction.

EPIDEMIOLOGY

Chronic allograft injury is the leading cause of death-censored graft failure late after transplantation. Its incidence and prevalence are difficult to determine because the onset is often insidious and difficult to define, especially when not every patient undergoes a biopsy. However, in some studies, “protocol” biopsies have been obtained in all patients at predetermined intervals after transplantation. In these studies, evidence of IF/TA was found in 50% of protocol biopsies at 3 months and in 94% of protocol biopsies at 1 year after transplantation in recipients treated with CNIs.⁸

PATHOLOGY

The histologic changes characteristic of chronic allograft injury are wide ranging and vary according to the underlying causes present. They include glomerulosclerosis, fibrointimal thickening of large and medium-sized arteries, and interstitial fibrosis and tubular atrophy (Fig. 103.2).

Banff Classification of Chronic Renal Allograft Pathology

The Banff schema was developed in the early 1990s to standardize reporting of transplant pathology; it incorporated other classification systems then in use,^{9,10} and with subsequent refinements, a scoring system for renal transplant pathology emerged. Lesions within individual anatomic compartments (vascular, glomerular, and interstitial) were classified as either acute or chronic and semiquantitatively scored by standardized definitions. Patterns of scored lesions, supported by specific pathologic features, were classified into a clinicopathologic diagnosis and graded. Chronic lesions representing sclerosing changes in the allograft were primarily defined by interstitial fibrosis and tubular atrophy and graded by severity and extent of tubulointerstitial damage into grade I (mild, 6% to 25% of cortex), grade II (moderate, 26% to 50%), and grade III (severe, >50% of cortical area). The schema also categorized other lesions, such as glomerulopathy, mesangial matrix increase, vascular fibrous intimal thickening, and arteriolar hyaline thickening. Patterns of scored lesions,

Banff Classification of Renal Allograft Pathology

1. Normal

2. Antibody mediated rejection

Documentation of circulating anti-donor, and C4d or allograft pathology
C4d deposition without morphologic evidence of active rejection (C4d+)
presence of circulating antidonor antibodies, no signs of acute or chronic T cell-mediated or antibody-mediated rejection

Acute antibody-mediated rejection

C4d+, presence of circulating antidonor antibodies, morphologic evidence of acute tissue injury, such as:

- I. ATN-like minimal inflammation
- II. Capillary and glomerular inflammation and/or thromboses
- III. Arterial - v3

Chronic active antibody mediated rejection

C4d+, presence of circulating antidonor antibodies, morphologic evidence of tissue injury such as:
Glomerular double contours and/or peritubular capillary basement membrane multilayering and/or interstitial fibrosis/tubular atrophy and/or fibrous intimal thickening

3. Borderline changes

Suspicious for acute T-cell mediated rejection
No intimal arteritis but foci or tubulitis (t1, t2 or t3 with i0 or i1)

4. T cell mediated rejection

Acute T cell mediated rejection

Type

- IA Interstitial infiltration and moderate tubulitis (i2 or i3 and t2)
- IB Interstitial infiltration and severe tubulitis (i2 or i3 and t3)
- IIA Mild to moderate intimal arteritis (v1)
- IIB Severe intimal arteritis (v2)
- III Transmural arteritis and/or fibrinoid change and/or smooth muscle necrosis

Chronic active T cell mediated rejection

"Chronic allograft arteriopathy"
Arterial fibrosis with mononuclear cell infiltration in fibrosis

5. Interstitial fibrosis and tubular atrophy, no specific etiology (formerly known as CAN)

Grade

- I Mild interstitial fibrosis and tubular atrophy (<25% of cortical area)
- II Moderate interstitial fibrosis and tubular atrophy (26%-50% of cortical area)
- III Severe interstitial fibrosis and tubular atrophy (>50% cortical area)

6. Changes thought not due to rejection - either acute or chronic (see fig. 103.8)

Figure 103.1 Banff classification of renal allograft pathology. (2007 update of original 1997 classification.) ATN, acute tubular necrosis; CAN, chronic allograft nephropathy.

supported by specific pathologic features, were then classified into a clinicopathologic diagnosis.^{11,12}

It is now recognized that use of the nonspecific term *chronic allograft nephropathy* undermined recognition of morphologic features that could enable diagnosis of specific causes of chronic graft dysfunction.⁷ Consequently, the schema has been modified (see Fig 103.1) to include various causes of chronic graft injury, such as:

- Chronic antibody-mediated rejection, described by basement membrane duplication in glomerular or peritubular capillaries in the presence of complement 4d deposition and antidonor HLA antibody.
- Chronic active T cell-mediated rejection, characterized by arterial intimal fibrosis with a mononuclear cell infiltrate.
- Interstitial fibrosis and tubular atrophy not otherwise specified.
- Nonimmune causes of injury, such as chronic CNI toxicity.

This classification provides a standardized and widely accepted framework for histologic analysis of renal allograft pathology. However, the pathology of a failing transplant represents a final common pathway of damage and injury from multiple overlaid mechanisms. In many cases, it can be impossible to assign a

specific cause; indeed, multiple causes of interstitial fibrosis and tubular atrophy will often coexist within the same biopsy specimen.

Transplant Glomerulopathy

The term *transplant glomerulopathy* was coined in 1970 for glomerular abnormalities specific to renal allografts and distinct from recurrent or *de novo* glomerulonephritis (GN).¹³ Transplant glomerulopathy is a characteristic element of chronic renal allograft pathology. Transplant glomerulopathy is characterized by duplication of glomerular capillary basement membrane, mesangial matrix expansion, and absence of immune deposits (Fig. 103.3). In addition, there is deposition of C4d in peritubular and glomerular capillaries (Fig. 103.4). Clinicopathologic studies suggest that transplant glomerulopathy is a manifestation of capillary injury occurring in conjunction with interstitial, peritubular capillary, and glomerular inflammation, although it may also occur independently of interstitial fibrosis, tubular atrophy, or transplant arteriopathy.¹⁴ On electron microscopy, there is expansion of the subendothelial space with deposition of flocculent or fibrillary material, interposition of mesangial cell cytoplasm in the lamina densa, and mesangial matrix expansion (Fig.

Figure 103.2 Histologic features of chronic allograft dysfunction and interstitial fibrosis/tubular atrophy with no evidence of specific etiology (IF/TA). **A**, Interstitial fibrosis and glomerulosclerosis. **B**, Fibrointimal proliferation in an intrarenal artery.

Figure 103.3 Transplant glomerulopathy: light microscopy. **A**, Note the mesangial expansion and thickening of the glomerular basement membranes (GBM). **B**, Note the GBM reduplication in capillary loops (between arrows).

103.5). Ultrastructural abnormalities characteristic of endothelial activation occur long before glomerular basement membrane (GBM) duplication and graft dysfunction are evident, implying that endothelial injury is the initial insult that resulted in GBM remodeling (see Fig. 103.5).¹⁵ An association between transplant glomerulopathy and peritubular capillary basement membrane duplication has been well described, suggesting that the process resulting in transplant glomerulopathy involves the entire glomerular and peritubular capillary beds.^{16,17}

Role of Protocol Biopsies

Many studies of chronic graft pathology have relied on biopsies performed for graft dysfunction. These studies have inherent bias because the immediate cause of graft dysfunction may not reflect the complex interactions between various factors causing cumulative damage, making it difficult to identify contributions of the different etiologic factors.⁸

Our understanding of the pathophysiologic process of graft injury has improved with the use of surveillance or protocol biopsies as a monitoring tool for pathologic change. Protocol biopsies enable assessment of individual risk factors by detecting early pathologic abnormalities when renal function is stable and individual factors may be in operation; these abnormalities can then be used as surrogate markers for chronic injury. Several studies have shown that chronic pathologic changes detected by surveillance biopsies at 3 months after transplantation, when allograft function is stable, predict poor long-term graft

survival,¹⁸⁻²⁰ whereas other studies have shown that subclinical rejection (defined as occurrence of histologic signs of acute rejection in patients with stable graft rejection) precedes long-term deterioration of graft function and that early intervention improves outcomes.²¹ The use of surveillance biopsies in the research setting has given insight into the causes of renal allograft injury and their interactions.²²

PATHOGENESIS

Factors associated with chronic graft injury are broadly categorized as nonimmune and immune. In most cases, the damage sustained by a renal graft is not the result of a single insult but rather the accumulated effect of multiple sequential or contemporaneous insults (Fig. 103.6) that are then modified by the kidney's limited healing response, which invariably involves fibrosis. This has led to the "cumulative damage" hypothesis that chronic allograft injury is the result of a series of time-dependent insults leading to nephron loss.²³ This loss of nephrons is progressive and accumulative and precedes glomerulosclerosis, a later event that follows increasing interstitial fibrosis and tubular atrophy.⁸ In this model, both the site of insult and the subsequent injury are compartment specific. This association between injury and compartment-specific damage is summarized in Figure 103.7.

Figure 103.4 Transplant glomerulopathy: C4d immunoperoxidase staining in association with chronic antibody-mediated rejection. Staining of glomerular capillaries and circumferential staining of peritubular capillaries are typical.

IMMUNE-INDEPENDENT FACTORS

There are many nonimmune factors that over the life of the graft lead to IF/TA. These are described here and are summarized in Figure 103.8.

Ischemia and Reperfusion Injury

Graft survival is lower in recipients with longer ischemic times; this effect is present even after adjustment for other factors, such as transplant era, donor type, recipient age, and major histocompatibility complex (MHC) mismatches.^{5,24,25} In protocol biopsies, acute tubular necrosis (ATN) is predictive of IF/TA²⁶ and has been identified as a cause of graft fibrosis at 3 and 12 months.^{26,27} In a German study in which 258 patients underwent biopsy at 6, 12, and 26 weeks, longer cold ischemic time was a risk factor for the development of IF/TA at 26 weeks.²⁸ Ischemia-reperfusion injury may also be a factor in immune-mediated injury as ischemia and oxidative injury resulting from reperfusion are associated with activation of the adaptive immune response, antigen-presenting cells and Toll-like receptors (TCRs), and release of proinflammatory cytokines, which can lead to acute rejection and subsequent IF/TA.²⁹ In deceased

Figure 103.5 Transplant glomerulopathy: electron microscopy. **A**, Section of glomerular capillary loop ($\times 24,000$) demonstrating mesangial interposition (*asterisks*), subendothelial expansion and new lamina densa (*double arrow*), and endothelial hypertrophy (*line*). **B**, A complete glomerular capillary loop (CL) with glomerular basement membrane (GBM) thickening (*single arrow*), endothelial hypertrophy (*double arrow*), expanded subendothelial space, mesangial interposition, and new lamina densa (*single arrow*). Apparent GBM duplication is due to mesangial interposition and formation of new lamina densa.

donor transplantation, brain death amplifies this response. Brain death results in an “autonomic storm” with release of catecholamines and a sympathetic response, which results in cytokine release, endothelial cell activation, and amplification of the ischemia-reperfusion injury.²⁹

Donor Age and Donor-Recipient Size Mismatching

Long-term graft survival is reduced in kidneys from older donors in both deceased donor and living donor transplants. This effect is attributed to a differential response to injury, impaired capacity to withstand stress, limited ability to repair structural damage, or amplification of external injury due to preexisting structural abnormalities. Reduced nephron mass resulting in glomerular hyperfiltration and hypertension with accelerated senescence is also a postulated mechanism.^{30,31} The effect of kidney size mismatching is thought to be related to insufficient numbers of nephrons within the donor kidney, which in turn leads to compensatory hyperfiltration.³² Although there are experimental data to support this hypothesis, the extent to which an inadequate number of nephrons contributes to chronic injury is unknown.

Risk Factors Associated with the Progression of Tubulointerstitial Damage and Renal Allograft Dysfunction	
Donor Factors	Deceased versus living donor Age Female sex Vascular disease Glomerular disease Brain death versus donation after cardiac death Nephron mass Ischemic time Delayed graft function
Recipient Factors	African American race Older age Male sex Diabetes mellitus HLA matching Antidonor antibodies Hypertension, hyperlipidemia, diabetes, smoking Compliance with treatment
Graft function	Serum creatinine at 1, 6, 12 months Change in serum creatinine between 6 and 12 months Change in GFR between 6 and 12 months GFR at 6 and 12 months
Evidence of graft injury	Acute rejection, especially vascular rejection and late rejection CMV disease BK virus nephropathy Calcineurin nephrotoxicity Doppler ultrasound resistive index >0.80 Proteinuria >500 mg/24 h
Graft pathology in first year	Subclinical rejection Nephrocalcinosis Arteriolar hyalinosis Interstitial fibrosis Tubular atrophy C4d binding Transplant glomerulopathy Recurrent or <i>de novo</i> glomerulonephritis

Figure 103.6 Risk factors associated with the progression of tubulointerstitial damage and renal allograft dysfunction. CMV, cytomegalovirus; GFR, glomerular filtration rate; HLA, human leukocyte antigen.

Tubulointerstitial Injury from BK Virus Nephropathy

BK virus is an endemic polyomavirus of high prevalence, low morbidity, long latency, and asymptomatic reactivation in immunocompetent individuals. It is seen increasingly in renal transplant recipients as more potent immunosuppression allows asymptomatic reactivation of primary infection and subsequent allograft dysfunction. BK virus nephropathy leads to IF/TA and needs to be considered in trying to identify the causes in an individual case.³³ The diagnosis and management of BK virus nephropathy are discussed further in Chapter 101.

Calcineurin Inhibitor Nephrotoxicity

CNI nephrotoxicity affects all histologic compartments of the transplanted kidney. Characteristic chronic CNI lesions include

medial arteriolar hyalinosis, striped interstitial fibrosis, global glomerulosclerosis, and tubular microcalcification unrelated to other causes, such as tubular necrosis and hyperparathyroidism.³⁴⁻³⁷ CNI-induced arteriopathy is characterized by nodular hyaline deposits in the media of afferent arterioles sufficient to cause narrowing of the vascular lumen.^{38,39} It is attributed to eosinophilic transformation and vacuolization of smooth muscle cells with subsequent necrosis. Arteriolar hyalinosis is the most reliable diagnostic marker of CNI nephrotoxicity. Confirmation of the diagnosis is made by exclusion of other causes, such as donor hyalinosis (which can be detected on the implantation biopsy specimen), diabetes, and hypertensive nephrosclerosis. Striped fibrosis is subjectively defined by a dense stripe of cortical fibrosis and atrophic tubules adjacent to normal cortex and is traditionally regarded as pathognomonic of CNI nephrotoxicity, but its appearance can be seen in any cause of fibrosis, especially if it is due to microvascular injury. It is likely that the associated arteriopathy and narrowing of the lumen contribute to development of fibrosis and atrophy following watershed infarcts within areas of ischemia. Local hypoxia leads to formation of free oxygen radicals, which promote cellular death by apoptosis. In addition, upregulation of transforming growth factor β (TGF- β) is considered an important etiologic factor in CNI toxicity.³⁴

Recurrent and *de novo* Glomerular Disease

Recurrent GN is diagnosed by exclusion of donor-transmitted disease and *de novo* GN. Its relative importance for graft loss increases as graft survival lengthens.⁴⁰ The clinical course and severity of recurrent glomerular disease often recapitulate the patient's native disease. Given that it is a relatively common occurrence and has implications for treatment and retransplantation, it should be looked for carefully in patients with a prior diagnosis of GN. Diagnosis and management of recurrent disease are discussed further in Chapter 104.

Deceased Donor Kidneys

Kidneys from living donors, regardless of their relationship with the recipients, survive longer than kidneys from deceased donors. Recipients of living donor kidneys have less late allograft failure and less histologic evidence of chronic allograft injury.⁴¹ This increased survival of living donor kidneys is multifactorial. They have reduced ischemia time and lack the negative influence of deceased donor brain death, which causes an upregulation of cytokines and growth factors in the kidney and other organs. In general, they do not have preexisting donor disease; and because there is more time involved in planning, they are more likely to be selected so that they avoid non-complement-binding antidonor antibodies, which may not be detected on the traditional complement-dependent cytotoxicity assay.

Delayed Graft Function

Delayed graft function, usually defined by the need for dialysis in the first week after transplantation, is a risk factor for IF/TA.²⁶ There are also independent associations between delayed graft function and late graft failure and between delayed graft function and graft failure that is mediated by acute rejection. Major risk factors for delayed graft function are prolonged cold ischemia time, donor age older than 50 years, and peak panel reactive antibodies greater than 50%.⁴² Ischemia and oxidative injury resulting from reperfusion of an ischemic kidney may cause an

Figure 103.7 Chronic allograft dysfunction and compartment-specific pathologic changes. The individual factors causing chronic allograft dysfunction (shown in the lower part of the figure) are active at different stages in the life of a transplant kidney. There is evidence that each factor predominantly damages specific compartments of the kidney (arrows) causing pathologic changes which ultimately lead to graft loss. CNi, calcineurin inhibitor. (Modified from reference 22.)

Pathologic Features of Specific Chronic Diseases Other than Rejection that Can Lead to Interstitial Fibrosis/Tubular Atrophy	
Cause	Pathology
Chronic hypertension	Arterial/fibrointimal thickening with reduplication of elastica, usually with small artery and arteriolar hyaline changes
Calcineurin inhibitor toxicity	Arteriolar hyalinosis with peripheral hyaline nodules and/or progressive increase in the absence of hypertension or diabetes Tubular cell injury with isometric vacuolization
Chronic obstruction	Marked tubular dilation; large Tamm-Horsfall protein casts with extravasation into interstitium and/or lymphatics
Bacterial pyelonephritis	Intratubular and peritubular neutrophils, lymphoid follicle formation
Viral infection	Viral inclusions on histology and immunohistology and/or electron microscopy

Figure 103.8 Pathologic features of specific chronic diseases that can lead to interstitial fibrosis/tubular atrophy (IF/TA). (Modified from reference 7.)

upregulation of MHC antigens or proinflammatory cytokines, predisposing to acute rejection.

Cardiovascular Risk Factors

The vasculopathy in chronic allograft injury resembles systemic vascular disease, raising the possibility that conventional cardiovascular disease (CVD) risk factors may be implicated.

Hypertension occurs in more than 50% of transplant recipients. In a multicenter, retrospective study of 29,751 kidney transplant recipients with 7 years of follow-up, elevated systolic and diastolic blood pressure (BP) was associated with chronic graft failure in a multivariate analysis.⁴³ Hypertension is associated with IF/TA. Dyslipidemias, including raised levels of total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglycerides, have been associated with late graft failure.⁴ Cigarette

smoking is associated with late renal allograft failure^{44,45} either by a direct toxic effect on the allograft or more likely mediated by hypertension or other cardiovascular (CV) risk factors. In health systems in which patients must meet the cost of their immunosuppressive medication, it is also possible that cigarette smoking may identify patients more likely to be non-compliant with immunosuppressive medications for socioeconomic reasons.

Proteinuria is an important diagnostic marker for late renal allograft failure⁴⁴ and is associated with histologic changes seen in chronic allograft injury.⁴⁶

IMMUNE-DEPENDENT FACTORS

Acute Rejection

Graft rejection leads to allograft damage, but its expression depends on its type, timing, severity, and persistence. Early acute cellular rejection, vascular or corticosteroid-resistant rejection, subclinical rejection, true chronic rejection, and late acute rejection all contribute to the burden of allograft injury. Interstitial cellular rejection is followed by interstitial fibrosis, and vascular rejection by increased vascular damage, contributing to injury.⁴⁷ Multiple and severe late acute T cell-mediated rejection episodes are predictive of chronic graft dysfunction more than early cellular rejection and acute vascular rejection, which have stronger associations with acute graft loss.^{48,49} There is compelling evidence from protocol biopsy studies that subclinical cellular rejection is an important factor in early graft loss and subsequent chronic graft injury.^{27,50} Subclinical rejection is defined as histologically proven acute rejection without concurrent renal dysfunction and is influenced by time after transplantation, prior acute rejection, HLA mismatch, and immunosuppression.²⁷ Interstitial lymphocyte infiltration may persist in some patients as true chronic cellular rejection, which is arbitrarily defined as subclinical rejection that persists beyond 1 year. Inflammatory mediators generate compartment-specific fibrosis, impaired graft function, and reduced survival.^{27,51} Untreated subclinical rejection inflicts permanent tubulointerstitial damage and fibrosis and is associated with a poorer prognosis.²⁷ Prompt diagnosis, early treatment, and readjustment of baseline immunosuppression have been associated with improved outcomes.⁵⁰

Chronic Antibody-Mediated Rejection

The contribution of donor-specific anti-HLA antibodies to allograft injury has been demonstrated in studies showing that presensitization and appearance of post-transplantation HLA antibodies are risk factors for early graft loss,^{52,53} hyperacute rejection,⁵⁴ and a higher incidence of primary nonfunction and decreased graft survival.⁵⁵ Stenotic arterial lesions have been described in recipients with circulating antibodies and late graft loss.⁵⁶ Several studies have attempted to demonstrate a temporal relationship between appearance of antibodies and subsequent graft dysfunction.^{57,58} The accepted diagnostic criteria for chronic antibody-mediated rejection include presence of circulating antidonor antibodies; diffuse positive C4d staining in the peritubular capillaries; and evidence of morphologic injury, which includes transplant glomerulopathy, peritubular capillary basement membrane multilayering, tubulointerstitial fibrosis, and arterial intimal fibrosis without duplication of lamina elastica interna (see Figs. 103.1 to 103.5). The time line for development of chronic antibody-mediated rejection includes appearance of antibody,

deposition of complement, graft dysfunction, and subsequent pathologic abnormalities.⁵⁹

Transplant Glomerulopathy

Transplant glomerulopathy and arteriopathy are the histopathologic abnormalities attributed to chronic antibody-mediated injury in renal allografts (see earlier discussion, [Pathology](#)). However, transplant glomerulopathy is itself an important cause of renal allograft loss and late graft dysfunction.⁶⁰ Although it is less common compared with nonspecific causes of IF/TA, transplant glomerulopathy is accompanied by a progressive decline in graft function, substantial or nephrotic-range proteinuria, hypertension, and shortened graft survival. Human studies report that transplant glomerulopathy is more common in sensitized patients with a broad range of anti-HLA antibodies and is particularly prevalent in those with donor-specific class II antibodies.¹⁴ The incidence is highest if both class I and class II antibodies are present or there has been prior acute antibody-mediated rejection.¹⁴ C4d deposition is reported in more than 50% of recipients with histologic features of transplant glomerulopathy or arteriopathy⁵²; circulating antidonor HLA antibody was identified in more than 80% of cases with diffuse staining for C4d. There is also a strong association between C4d deposition and peritubular capillary multilamination of more than five layers.⁵² In patients who develop transplant glomerulopathy, loss of graft function occurs before development of widespread glomerulosclerosis, and the appearance of transplant glomerulopathy on a biopsy specimen is generally followed by an accelerated rate of graft loss.⁶⁰

Histologic Progression of Chronic Graft Injury

Our current understanding of the natural history and progression of chronic renal allograft injury comes from protocol biopsy studies evaluating the causes and correlates of chronic allograft dysfunction. A study of more than 900 protocol biopsies from recipients of simultaneous kidney-pancreas transplants has provided valuable insight into the relationships between graft fibrosis, arteriolar damage, and glomerular dysfunction.⁸ This study showed that allograft injury occurred in two distinct phases: an early phase characterized by tubulointerstitial damage; and a late phase, which primarily involves the microvascular compartments (i.e., glomerular, peritubular, and interstitial capillary networks), leading to progressive interstitial fibrosis, tubular atrophy, and glomerulosclerosis. Causes of early tubulointerstitial injury include preexisting conditions in the donor kidney, such as warm and cold ischemia time and quality of donor organ preservation, as well as postimplantation events, such as early rejection, delayed graft function, and immunosuppressive toxicity. In contrast, graft injury in the late phase is primarily attributed to the effects of CNI toxicity and persistent and progressive subclinical inflammation.⁶¹ This is summarized in [Figure 103.7](#).

Mechanisms of Graft Injury

Graft dysfunction typically results from cumulative tissue injury arising from several pathogenic insults occurring in specific histologic compartments, modified by the kidney's healing response to the injury, alloimmunity, and immunosuppression. The starting condition of the transplanted kidney (which includes input organ quality and acute early events) and subsequent immune and nonimmune stressors contribute to loss of structural integrity of the graft and subsequent failure.²³

Injury to any key component of a nephron results in functional failure of the whole unit. Individual nephrons fail because of glomerulosclerosis, transplant glomerulopathy, or loss of tubular components. Segmental glomerular injury leads to capsular adhesions, misdirection of ultrafiltrate, and reduction in overall functional efficiency.⁶² Tubular malfunction is caused by localized apoptosis, tubular atrophy, or luminal obstruction from cellular debris leading to loss of tubular basement membrane (TBM) integrity and leakage.⁶³

Chronic ischemia plays a major role in the initiation and perpetuation of glomerular and tubulointerstitial injury. Vascular narrowing due to glomerulosclerosis, CNI-induced arteriolar hyalinosis,³⁷ fibrointimal hyperplasia of small arteries, and cyclosporine-induced vasoconstriction cause ischemic injury, peritubular capillary loss,⁴⁷ and subsequent tubulointerstitial injury. An important aspect of graft injury is the process of tissue repair after injury. Repeated episodes of acute injury are followed by partial or incomplete resolution of inflammation, resulting in a vicious circle of inflammation, enhanced expression and recognition of alloreactive molecules, and further injury.³⁰ Evidence of an impaired healing process has been provided by studies that show an association between the presence of inflammatory cells within areas of fibrosis (activated fibrosis) and progressive damage, functional impairment, and reduced graft survival.²⁷ Variations in response to injury and impaired capacity to withstand stress because of increased donor age also contribute to limited ability to repair structural damage, causing further amplification of external insults by preexisting abnormalities and perpetuation of the vicious circle.

CLINICAL MANIFESTATIONS

Chronic allograft injury usually presents as a decline in glomerular filtration rate (GFR) or an increase in urine protein excretion. There are no specific clinical features of chronic allograft injury. All too often, it is first detected when it is already far advanced because clinical methods for detection of early declines in GFR are relatively insensitive. Serum creatinine remains the routine parameter for detection of changes in GFR in kidney transplant recipients. Whereas an acute rise in serum creatinine is a relatively sensitive albeit nonspecific indicator of acute allograft dysfunction from any cause, chronic changes in serum creatinine are not very sensitive for detection of chronic allograft dysfunction. Furthermore, patients with chronic allograft injury may have lower muscle mass, resulting in lower serum creatinine values than expected for the GFR. Estimation of GFR by the Nankivell formula or the Modification of Diet in Renal Disease (MDRD) formula may be helpful to supplement information from serial serum creatinine estimations. The value and limitations of measurement and estimation of GFR are discussed further in Chapter 3.

Proteinuria may also be the first manifestation of chronic allograft injury. Few studies have prospectively evaluated proteinuria as a tool for screening to detect chronic injury or other causes of allograft dysfunction. IF/TA is found in more than half of patients who undergo allograft biopsy for proteinuria and in 40% of those who have nephrotic-range proteinuria.⁶⁴ Transplant glomerulopathy is almost always accompanied by proteinuria. Except for proteinuria, the urinalysis is usually unremarkable in chronic allograft dysfunction. Clinical and histologic factors that are predictive of chronic allograft dysfunction are summarized in Figure 103.6.

Differential Diagnosis of Chronic Allograft Dysfunction

Prerenal reversible hemodynamic dysfunction

- Dehydration
- Congestive cardiac failure
- Nonsteroidal anti-inflammatory drugs
- Antihypertensive medication
- Graft renal artery stenosis

Intrinsic renal parenchymal disease

- Acute rejection
- Calcineurin inhibitor toxicity
- Other nephrotoxic agents (e.g., lithium)
- Recurrent renal disease
- De novo* glomerulonephritis
- Drug-induced interstitial nephritis
- Viral infections, CMV, polyomavirus
- Bacterial pyelonephritis
- Lymphomatous infiltrate
- Late acute rejection, either iatrogenic or due to noncompliance

Obstructive renal disease

- Ureteral stenosis
- Prostatic hypertrophy
- Other causes of bladder outlet obstruction (e.g., cancer, calculi)
- Ureteral or bladder leak
- Ureteral polyomavirus infection

Figure 103.9 Differential diagnosis of chronic allograft dysfunction. CMV, cytomegalovirus.

DIFFERENTIAL DIAGNOSIS

Because the etiology of chronic allograft dysfunction is multifactorial, any specific diagnosis is made by combination of a biopsy with a review of the patient's past history to identify important etiologic factors, such as preexisting donor disease, prior rejection, and high-titer anti-HLA antibodies, as well as issues not related to alloimmunity, such as CNI toxicity, *de novo* GN, or recurrent renal disease. Chronic allograft dysfunction is common and can have many causes other than IF/TA. However, if it is left untreated, it can ultimately result in renal injury, which in turn will heal by scarring and interstitial fibrosis. The differential diagnosis of IF/TA is summarized in Figure 103.9.

Prerenal Causes

Prerenal causes of allograft dysfunction include reversible hemodynamic alterations that may occur from dehydration or congestive heart failure (CHF). Graft renal artery stenosis or stenosis of arteries proximal to the kidney allograft can cause a decline in kidney function. This is usually associated with difficult-to-control hypertension. Rarely, cholesterol emboli can present as a decrease in function late after transplantation.

Intrinsic Renal Causes

Acute rejection can occur late after transplantation and present as a gradual rise in serum creatinine with or without proteinuria. Late acute rejection is often the result of the patient's noncompliance with immunosuppressive medications. The diagnosis and management of acute deterioration of allograft function are discussed further in Chapters 99 and 100.

Viral infections, including cytomegalovirus (CMV) and polyomaviruses, especially BK virus, can also cause acute or chronic graft dysfunction. BK virus infection is suspected on finding BK virus in the serum or urine and confirmed by detecting virus in kidney tissue with either antibody staining or *in situ* hybridization. Histologic changes associated with BK virus nephropathy can resemble acute rejection, but renal tubular cell cytopathic changes are features that point to BK virus nephropathy. The presence of SV40 antigen, which can be detected routinely by immunohistochemistry, will differentiate between BK virus nephropathy and acute cellular rejection.

Allergic interstitial nephritis, often medication induced, and acute bacterial pyelonephritis are usually differentials for acute rather than for chronic allograft dysfunction.

Proteinuria, with or without a decline in kidney function, may be caused by *de novo* or recurrent glomerular diseases. The most common recurrent glomerular disease causing chronic allograft injury and graft loss is IgA nephropathy. Other recurrent diseases in the renal transplant are discussed in Chapter 104.

Postrenal Causes

Postrenal causes should also be considered. Although it is uncommon, ureteral obstruction can occur late after transplantation. Bladder dysfunction or prostatic hypertrophy can also cause allograft dysfunction and can lead to IF/TA.

TREATMENT

Strategies for the management of chronic allograft dysfunction rely on minimization of exposure to risk factors as there is no effective specific treatment. Current recommendations for the treatment of chronic allograft dysfunction are summarized in Figure 103.10.

Prevention

The use of young living donors and optimal HLA matching are helpful but often impossible in this era of long waiting times and donor shortage. Prolonged cold ischemic times should be avoided as much as possible to reduce the risk of delayed graft function. An effective strategy for minimization of IF/TA is early recognition and treatment of acute rejection. Effective immunosuppression that reduces the incidence and severity of acute cellular rejection is crucial as less alloimmune-mediated inflammation will result in less interstitial fibrosis and tubular atrophy. Surveillance biopsies have resulted in improved diagnosis and early treatment of subclinical acute rejection, a major cause of chronic injury. In units where protocol biopsies are not undertaken, there should be a high index of suspicion and a low threshold for performing diagnostic biopsies, especially in the first 6 months after transplantation. Prompt treatment of subclinical cellular rejection, when it is identified, has been shown to limit the degree of chronic damage at later time points.^{50,65} Increased surveillance in high-risk patients, such as those receiving organs from older donors, may allow early intervention. If protocol biopsies are not being routinely performed, a biopsy should be undertaken if graft function fails to reach an acceptable baseline.

Maintenance Immunosuppression

Treatment of established IF/TA relies on modification of immunosuppression protocols, such as CNi avoidance or dose

Treatment Recommendations for Chronic Allograft Dysfunction

Minimize acute rejection

Use adequate immunosuppression
Monitor graft function and urine protein
Investigate with biopsy for unexplained increases in serum creatinine, failure of serum creatinine to fall to acceptable levels, or proteinuria

Minimize subclinical rejection

Use adequate immunosuppression
Re-evaluate immunosuppression if subclinical rejection detected
Consider use of protocol biopsies or have high index of suspicion

Minimize or eliminate CNi

Consider low-dose tacrolimus with mycophenolate mofetil and prednisolone
Consider substitution of CNi with mTOR inhibitor if clinically appropriate
Consider withdrawal of CNi if immunologically very low risk (e.g., HLA-identical graft)

Control BP

Aim for BP <130/80 mmHg
Consider ACE inhibitor or ARB if proteinuria >500 mg/24 h

Treat other nonimmunologic risk factors

Maintain LDL cholesterol <3.5 mmol/l
Cessation of smoking
Maintain compliance

Figure 103.10 Treatment recommendations for chronic allograft dysfunction. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; BP, blood pressure; CNi, calcineurin inhibitor; HLA, human leukocyte antigen; LDL, low-density lipoprotein; mTOR, mammalian target of rapamycin.

reduction. A meta-analysis suggested a beneficial effect of CNi withdrawal and replacement with mycophenolate mofetil (MMF) or sirolimus in minimizing CNi toxicity.⁶⁶ However, the recent CONVERT trial suggests that CNi avoidance and substitution with sirolimus after the development of IF/TA result in at best modest improvements in graft function.⁶⁷ Use of MMF with or without CNi reduction results in improved graft function and altered chronic transplant histology.^{68,69} The SYMPHONY trial showed that low-dose tacrolimus in combination with MMF and prednisolone provided the best outcomes in patients with standard immunologic risk.⁷⁰ Patients without evidence of rejection may benefit from use of low-dose tacrolimus or, alternatively, avoidance of CNi altogether by substitution of an mammalian target of rapamycin (mTOR) inhibitor.

Apart from alterations in immunosuppression, effective management of comorbidities may help preserve kidney function. Efforts should be directed at BP control, treatment of hyperlipidemia, smoking cessation, and optimal glycemic control (management of these issues in transplant patients is discussed further in Chapter 102). Registry data suggest that prevention of smoking, reduction of serum cholesterol to less than 200 mg/dl (5.2 mmol/L), and lowering of BP to less than 130/80 mm Hg will improve long-term graft survival.

Proteinuria

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are used in native kidney disease to

reduce proteinuria and to slow progression to renal failure; however, there are not yet any randomized controlled studies showing that they slow the rate of progression of chronic renal allograft injury. In fact, registry data suggest that the addition of ACE inhibitors or ARBs does not result in improved graft outcomes.⁷¹ By contrast, a meta-analysis of trial data suggests that calcium channel blockers (CCBs) reduced graft loss and improved GFR, whereas the data regarding ACE inhibitors were inconclusive.⁷²

Recurrent Disease in Kidney Transplantation

Steven J. Chadban, Henri Vacher-Coponat

Kidney transplantation is a treatment, not a cure. Although transplantation may restore kidney function to the recipient, it does not necessarily remove the cause of the recipient's original kidney disease. Glomerulonephritis (GN) and diabetes are the two leading causes of end-stage renal disease (ESRD) worldwide and are the primary diseases afflicting the majority of patients considered for kidney transplantation. Both diseases may recur despite the different antigenic make-up of the new kidney and the altered states of recipient immunity and glucose metabolism due to immunosuppression.

The longer that a transplant remains *in situ*, the more likely it is to be affected by recurrence. As graft survival rates have increased during the past 30 years, mostly as a result of more effective antirejection therapies that prevent early graft loss, the incidence of recurrence has grown.¹ Within cohorts reassessed over time, an increase in the prevalence of recurrent disease with longer follow-up is also evident. An analysis of U.S. Renal Allograft Disease Registry data examining GN recurrence demonstrated a prevalence of 2.8% at 2 years, 9.8% at 5 years, and 18.5% at 8 years of follow-up after transplantation, and such patients were twice as likely to experience graft failure compared with those without recurrence.²

Recurrence has a powerful impact on transplant survival and one that is increasingly apparent with time after transplantation. In an analysis of data from the Australian registry (ANZDATA) including more than 1500 patients with biopsy-proven GN who received a kidney transplant, biopsy-proven recurrence was found to cause graft loss in 0.5% within 1 year after transplantation, 3.7% within 5 years, and 8.4% within 10 years (Fig. 104.1).³ This study and several others have found recurrent disease to be the third most common cause of graft failure beyond the first year after transplantation, behind death with a functioning graft and chronic allograft nephropathy (CAN) but substantially ahead of acute rejection (see Fig. 104.1).³

This chapter reviews the pathogenesis, clinical features, diagnostic and management issues, and outcome data of relevance to clinicians and their patients in contemplating transplantation as a treatment of kidney failure caused by diseases with a propensity to recur.

De novo GN and new-onset diabetes after transplantation (NODAT) may also affect the transplanted kidney, although both are relatively uncommon. Both conditions may be difficult to distinguish from recurrence and indeed from CAN and are discussed under differential diagnosis. Like recurrent disease, both appear to increase in prevalence with time after transplantation. Given the high incidence of NODAT coupled with general increases in graft survival,⁴ it is possible that *de novo* diabetic nephropathy in particular may become a significant clinical

problem in the future. However, present data suggest that the major impact of NODAT in the first 10 years after transplantation is an increase in cardiovascular mortality with little impact on death-censored graft failure.⁵

DEFINITIONS

The diagnosis of recurrence almost invariably requires histologic demonstration of the same disease involving both the native and transplanted kidneys. In addition, the diagnosis of recurrence causing graft failure requires a clinical decision that recurrence was the dominant contributor to graft loss (other contributors may be present, such as CAN). A histologic diagnosis of the primary kidney disease is not obtained for all patients with ESRD, and the majority of transplant recipients do not undergo biopsy to look specifically for recurrent disease (which may require immunohistologic and electron microscopic examination of the biopsy specimen).¹ Coupled with the tendency of clinicians to make a clinical diagnosis of CAN and thereby to avoid biopsy in patients with declining graft function and proteinuria, the true incidence of disease recurrence is not known and is almost certainly underestimated by existing literature.

Additional factors cloud the available evidence. Many reports of disease recurrence are retrospective, single-center studies. Recall bias and incomplete documentation, changes in practice over time, and peculiarities of local patient populations and local practices may limit relevance to other populations. The most definitive reports have come from analyses of the large registry databases of Europe, the United States, and Australia. Registries capture data on large numbers of patients but are subject to bias. Factors that may introduce bias include unit participation rates; quantity and type of data collected; accuracy, uniformity, and consistency of reporting by units; and reliability of data entry. How recurrence is defined and diagnosed and which outcomes are measured are crucial. For example, IgA nephropathy (IgAN) recurred in 58% of cases in one series in which all recipients underwent biopsy⁵ but in approximately 25% of cases in which biopsy was performed only when clinically indicated. When graft loss due to IgAN recurrence is the outcome measure, the risk decreases to approximately 10% at 10 years of follow-up.³ Thus, definition of recurrence, outcome measures, study design, and source of data all need to be considered in assessing the published literature.

RECURRENT GLOMERULONEPHRITIS

Virtually all recognized forms of GN may recur after transplantation; however, the rate and consequences of recurrence vary

Figure 104.1 Recurrent glomerulonephritis and other causes of graft failure. Kaplan-Meier analysis of the relative contributions of acute rejection, glomerulonephritis recurrence, death, and chronic allograft nephropathy to graft loss during the first 10 years after transplantation among patients who underwent transplantation because of end-stage renal disease caused by glomerulonephritis. (Modified with permission from reference 3.)

Figure 104.2 Primary glomerulonephritis and graft failure. Kaplan-Meier analysis of freedom from graft loss caused by recurrent glomerulonephritis during the first 10 years after kidney transplantation among patients with a primary diagnosis of glomerulonephritis. FSGS, focal and segmental glomerulosclerosis; IgAN, IgA nephropathy; MN, membranous nephropathy; MPGN, membranoproliferative glomerulonephritis; PIC GN, pauci-immune crescentic glomerulonephritis. (Modified with permission from reference 3.)

enormously. For example, anti-glomerular basement membrane (GBM) disease (Goodpasture's disease) recurs only rarely, but when it does, it is likely to cause rapid graft loss. In contrast, dense deposit disease (membranoproliferative GN type II, dense deposit disease) recurs in more than 80% of cases; however, the disease tends to be very slowly progressive, and graft survival beyond 10 years is typical. Numerically, recurrence of focal and segmental glomerulosclerosis (FSGS), IgAN, and membranous nephropathy (MN) are the most frequently encountered clinical problems (Fig. 104.2).

Factors in addition to the underlying type of GN may influence the risk of recurrence. Time of follow-up is clearly important and may be related to the duration of exposure of the graft to the nephritogenic factors responsible for GN.¹ In general, grafts that are lost early because of rejection are exposed relatively briefly and rarely develop recurrence. In contrast, those grafts that survive long term are exposed longer to nephritogenic factors and are more likely to develop recurrent GN. Consistent with this concept, recipients of HLA-identical transplants rarely suffer rejection, enjoy prolonged graft survival, but have a high rate of recurrent GN.⁶ In one report of HLA-identical recipients, recurrent GN was present in 36% to 42% of those in whom biopsy was performed and resulted in 24% of graft losses, being the second most frequent cause of graft loss after death in this group.⁶ Patients suffering first graft loss from recurrent GN are also at higher risk of recurrence and of graft loss due to recurrence in a subsequent graft.

The impact of choice of immunosuppressive agents may be significant; however, data in this area are sparse. Given that immune mechanisms contribute to the pathogenesis of most types of GN and that immunosuppression is effective in the treatment of several types, it is logical that immunosuppression in general probably decreases the incidence and severity of recurrence after transplantation. U.S. registry data (U.S. Renal Data System) on the impact of individual immunosuppressive agents on the incidence of recurrence failed to demonstrate superiority of any one agent over others.⁷ Induction therapy may be one exception to this finding as a small, retrospective study found rabbit antithymocyte globulin to be associated with a lower risk of IgAN recurrence compared with either anti-CD25 antibodies or no induction.⁸ *Post hoc* analyses of corticosteroid withdrawal trials suggest that this strategy does not lead to increased rates of recurrence.⁹ Inclusion or addition of cyclophosphamide has been effective in the management of recurrent vasculitis affecting the graft.¹⁰ Of major interest and concern is the tendency for patients maintained on (or particularly switched to) sirolimus to develop proteinuria and renal dysfunction. This effect appears to be more common among those with a primary diagnosis of GN, suggesting that sirolimus may either facilitate recurrence or, more likely, accelerate its impact on the graft.¹¹ Effects of individual agents are likely to be disease specific, and much needs to be learned in this area.

Strategies to reduce the risk of recurrence have been reported. Bilateral native nephrectomy as a means of eliminating persistent antigenic stimulation appears unhelpful; indeed, nephrectomized patients experienced a higher incidence of recurrence compared with those with native kidneys left *in situ* in one large single-center, retrospective study.¹² Induction of disease remission before transplantation and prolonged time on dialysis before transplantation, both aimed at permitting disease "burnout," do not appear to be effective except in the case of anti-GBM disease (Goodpasture's disease), in which a delay in transplantation until the patient has been serologically negative for at least 6 months virtually eliminates the risk of recurrence.³ Avoidance of living related donation has been debated for years but overall appears not to have any impact on risk of recurrence.¹³

Clinical Features and Differential Diagnosis

As is the case with GN in native kidneys, proteinuria, hematuria, and deterioration in kidney function are the cardinal manifestations of recurrent GN. The pattern of renal and extrarenal manifestations is frequently similar to that of the native disease, except

Differential Diagnosis of Recurrent Glomerulonephritis					
Diagnosis	Frequency and Timing	Clinical Features	Lab Features	Biopsy Features	Management
Recurrent glomerulonephritis	Common; variable timing, days to years	Proteinuria, hematuria, renal impairment, hypertension	Similar to primary glomerulonephritis; serology may be negative	Same as primary glomerulonephritis ^{4,5}	Disease specific
<i>De novo</i> glomerulonephritis	Uncommon; variable timing but typically later than recurrence	Proteinuria, hematuria, renal impairment	Type specific	Type specific ^{4,5,8}	Antiprotection strategies (see Chapter 69)
Chronic allograft nephropathy	Very common; increasing incidence with time	Hypertension, proteinuria, renal impairment Calcineurin inhibitor exposure		Tubulointerstitial fibrosis, arteriolar hyalinosis, transplant glomerulopathy	Minimize calcineurin inhibitor and antiprotection strategies (see Chapter 69)
Graft pyelonephritis	Uncommon Typically early after transplantation	Fever, pyuria, renal impairment	Positive blood or urine cultures	Neutrophil infiltration	Antibiotics
BK nephropathy	Uncommon; typically 1–5 yr after transplantation	Renal impairment, decoy cells in urine	Serum BK PCR positive	Tubulitis with tubular cell atypia and inclusions, normal glomeruli	Minimize immunosuppression and ? antiviral drugs
Acute rejection	Common; early	Renal impairment, oliguria	Nonspecific	Tubulitis ± vasculitis ¹⁵	Increase immunosuppression
Renal tumor/PTLD	Uncommon, rare; early or late	Renal impairment, renal mass	Anemia, EBV positive	Atypical cells, mitoses, monoclonality	Minimize immunosuppression, ? chemotherapy

Figure 104.3 Differential diagnosis of recurrent glomerulonephritis. EBV, Epstein-Barr virus; PCR, polymerase chain reaction; PTLD, post-transplantation lymphoproliferative disease.

that in the opinion of the authors, the rate of progression may in general be slower. Extrarenal features of the primary condition may recur, such as thrombocytopenia and hemolysis in hemolytic-uremic syndrome and extrarenal vasculitis in recurrent Wegener's granulomatosis. Serology may be helpful in some cases, such as anti-GBM antibody detection in Goodpasture's disease, but it may be inconsistent in others, such as recurrent lupus nephritis.

The differential diagnosis of recurrent GN is clinically important as management may vary according to the diagnosis (Fig. 104.3). CAN and diabetic nephropathy, recurrent or *de novo*, may both present with progressive graft dysfunction, proteinuria, and hypertension and may therefore be clinically indistinguishable from recurrence. *De novo* GN should also be considered. Viral diseases of the kidney, particularly BK nephropathy, are an important alternative to consider as a reduction in immunosuppression and specific antiviral therapy may provide benefit. The need to exclude obstructive uropathy and tumors involving the graft warrants an ultrasound scan. Finally, recurrence may coexist with CAN or calcineurin inhibitor toxicity. Indeed, every condition that can lead to chronic graft dysfunction should be considered in the differential diagnosis of recurrence (see Fig. 104.3 and Chapter 103).

Histologic evidence of recurrence is required in all cases. Biopsy can provide the diagnosis, exclude alternative diagnoses that may require different approaches to treatment, and provide important prognostic information pertinent to the affected graft and also relevant to any future consideration of retransplantation. Full evaluation of the biopsy specimen by light microscopy, immunohistology, and electron microscopy is desirable and in many cases essential to confirm recurrence.¹⁴ Light microscopy and immunohistology are necessary to differentiate recurrent

from *de novo* GN, rejection, and calcineurin inhibitor toxicity. The presence of tubulitis should suggest acute rejection. CAN may produce chronic interstitial inflammation and transplant glomerulopathy, which may be indistinguishable from MPGN by light microscopy (Fig. 104.4; see also Chapter 103). The use of immunohistology to define the immunoglobulin and complement component content of immune deposits and electron microscopy to establish the structure of basement membrane and location of deposits may clarify the diagnosis.¹⁴ Histologic appearances are typically no different from the patterns of GN in native kidneys and are illustrated in the relevant chapters of Section IV, Glomerular Disease. The risk of recurrence in common patterns of renal disease is summarized in Figure 104.5.

RECURRENCE OF SPECIFIC GLOMERULAR DISEASES

IgA Nephropathy and Henoch-Schönlein Purpura

IgAN is the most common form of GN leading to ESRD, and these patients are frequently transplant recipients. Histologic recurrence is frequent and increases with time; one study in which all recipients were subjected to protocol biopsy found recurrence in 58%.¹⁵ Recurrence is difficult to predict. Patient characteristics, pretransplantation course, serum IgA glycosylation, and angiotensin-converting enzyme genotype have been found to have no predictive value.^{1,15,16} Choice of immunosuppression after transplantation and post-transplantation course appear to have no impact,⁷ although observational data suggest that induction with antithymocyte globulin may afford relative protection.⁸ Living related donor transplantation has been associated with an increased risk of recurrence and graft loss in some

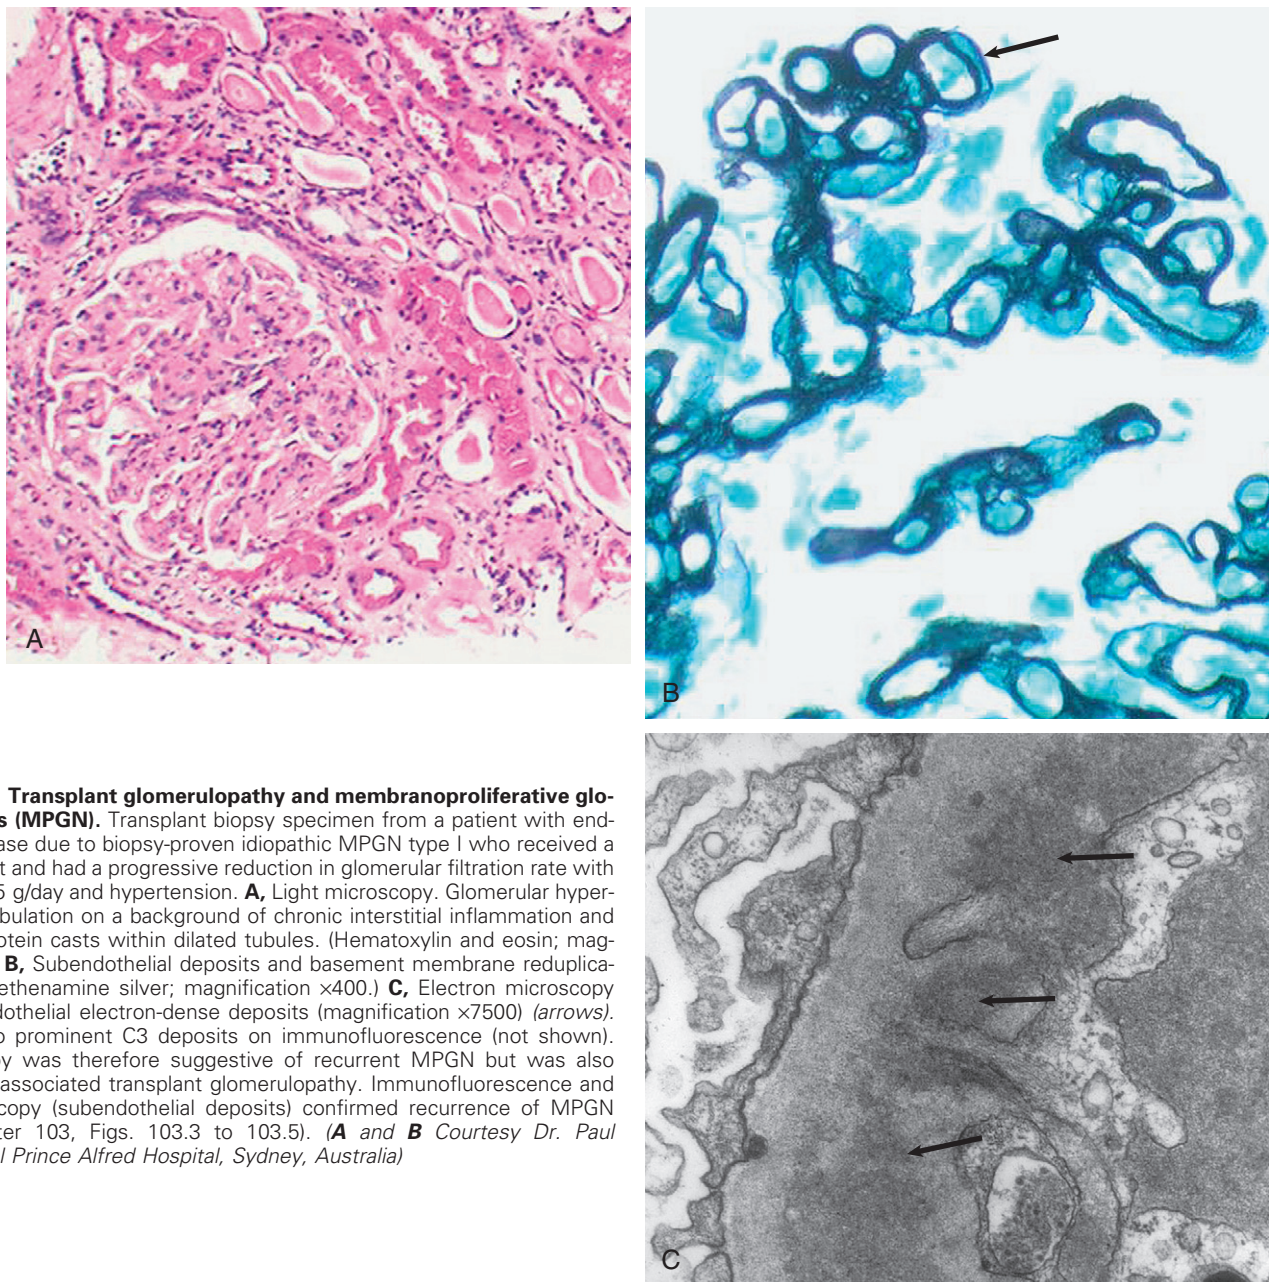

Figure 104.4 Transplant glomerulopathy and membranoproliferative glomerulonephritis (MPGN). Transplant biopsy specimen from a patient with end-stage renal disease due to biopsy-proven idiopathic MPGN type I who received a kidney transplant and had a progressive reduction in glomerular filtration rate with proteinuria of 1.5 g/day and hypertension. **A**, Light microscopy. Glomerular hypercellularity and lobulation on a background of chronic interstitial inflammation and fibrosis, with protein casts within dilated tubules. (Hematoxylin and eosin; magnification $\times 100$.) **B**, Subendothelial deposits and basement membrane reduplication (arrow). (Methenamine silver; magnification $\times 400$.) **C**, Electron microscopy showing subendothelial electron-dense deposits (magnification $\times 7500$) (arrows). There were also prominent C3 deposits on immunofluorescence (not shown). Light microscopy was therefore suggestive of recurrent MPGN but was also consistent with associated transplant glomerulopathy. Immunofluorescence and electron microscopy (subendothelial deposits) confirmed recurrence of MPGN (compare Chapter 103, Figs. 103.3 to 103.5). (**A** and **B** Courtesy Dr. Paul McKenzie, Royal Prince Alfred Hospital, Sydney, Australia)

series but not in others³ and does not justify the avoidance of living related donor transplantation in patients with IgAN.

The clinical expression of disease is variable and time dependent. Graft loss within the first 3 years after transplantation is uncommon (see Fig. 104.2), although it can be seen, particularly when there is extensive crescentic GN before transplantation or after previous graft loss due to recurrence.¹⁶ The longer term outlook is not benign as progressive graft loss over time has been documented by all major studies. In one registry study that included 587 subjects with biopsy-proven IgAN, the risk of graft loss due to IgAN recurrence was approximately 10% within 10 years after transplantation.³

Recurrence of Henoch-Schönlein purpura (HSP) nephritis is less well characterized but appears to be similar to IgAN in all respects. The largest report that pooled patients from Belgium

and Japan found recurrence in 35% and graft loss in 11% at 5 years of follow-up.¹⁷

Treatment of recurrent IgAN and HSP has not been systematically evaluated, and specific therapies, such as corticosteroids, mycophenolate mofetil (MMF), fish oil, and antiplatelet agents, cannot be recommended. The use of nonspecific measures to prolong kidney survival, such as tight blood pressure control, renin-angiotensin system (RAS) blockade, and avoidance of nephrotoxins, is appropriate.

Membranous Nephropathy

Data on recurrent MN are clouded by two key issues: the small number of subjects in reported series and the frequency of *de novo* MN after transplantation. *De novo* MN has been reported

Recurrent Diseases in Renal Transplants and Effects on Graft Survival		
Disease	Clinical Recurrence Rate (%)	Graft Loss in Recurrent Disease (%)
Primary focal segmental glomerulosclerosis	20–50 (children), 10–15 (adults)	40–50
Membranoproliferative glomerulonephritis		
Type I	20–30	30–40
Type II	80	20, often late
Hemolytic-uremic syndrome (HUS)		
Classical D ⁺ HUS	0–13	Uncommon
Atypical D ⁻ HUS	30–50	55–100
Familial HUS	57	Approaching 100
IgA nephropathy	30–40, increases with longer duration of follow-up (30%–60% histologic recurrence rate)	16–33
Henoch-Schönlein purpura	Rare (despite 50% histologic recurrence rate)	Rare
Membranous nephropathy	10–29 (histologic recurrence may be more common)	Up to 50
Systemic vasculitis, including Wegener's granulomatosis and microscopic polyangiitis	10–20	20–50
Anti-GBM disease (Goodpasture's disease)	<5	50
Systemic lupus erythematosus	1–30	Rare
Amyloidosis	25	10–20

Figure 104.5 Recurrent diseases in renal transplants and effects on graft survival.

in 2% to 15% of transplant recipients and tends to present more insidiously and later than recurrent MN.¹⁸

The largest series (pooled from centers in Belgium and France) reported a recurrence rate of 29% in 30 patients at 3 years after transplantation¹⁸; among those affected, graft loss was 38% at 5 years and 52% at 10 years of follow up. Recurrence is a significant clinical event causing proteinuria, nephrotic syndrome, and graft loss in 12% of recipients within 10 years after transplantation.³ Clinical factors including pretransplantation disease course, duration of dialysis, HLA genotype, graft source, and immunosuppression are not predictive of risk. However, those with a previous graft loss due to recurrence are at high risk if they are retransplanted.¹⁹

Management of recurrent MN is based on anecdotal reports and extrapolation of data on the management of native kidney MN. Spontaneous remissions appear to be less common. The cumulative exposure to immunosuppressive therapy should be considered as these patients may be at increased risk of lymphoma. Live donor transplantation appears warranted for first grafts but, in the opinion of the authors, should probably be avoided for second grafts if the first was lost early because of recurrence.

Focal Segmental Glomerulosclerosis

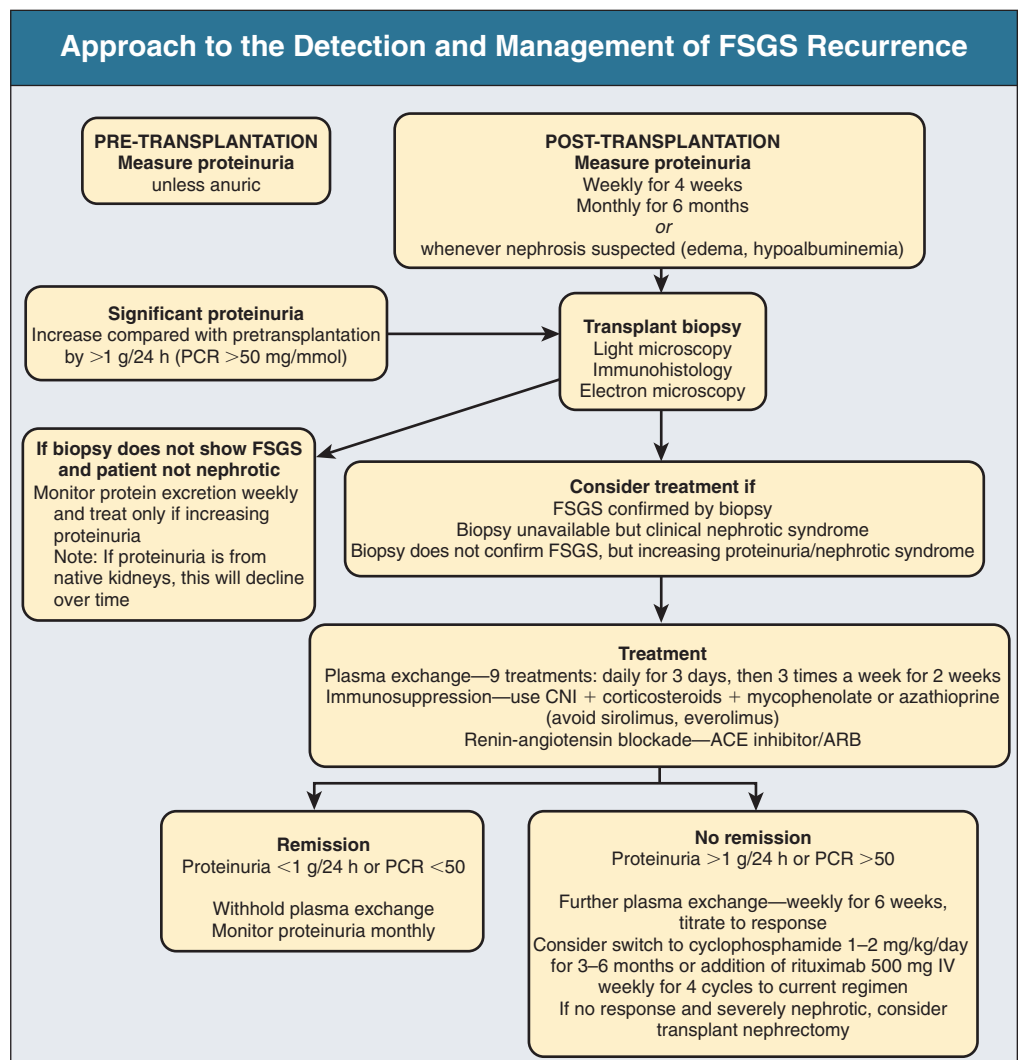

Patients with renal failure due to FSGS incur a risk of recurrence of 20% to 30% for first transplants.^{20,21} FSGS is a heterogeneous group of conditions. Those with familial or sporadic forms associated with mutation of slit diaphragm proteins such as podocin, those with FSGS secondary to vascular disease, and those with a very slow rate of progression are at substantially lower risk; whereas patients with an aggressive initial course (heavy proteinuria and renal failure within 3 years of onset), patients who are younger than 15 years, and patients with mesangial hypercellularity on biopsy or with recurrence in a previous graft are at

greatest risk.^{20,21} The rate of recurrence is more than 75% in subsequent grafts when the first graft was lost as a result of recurrence.²² Living related donor transplantation has been implicated as a risk factor for recurrence; however, a major analysis of U.S. registry data (U.S. Renal Data System) refutes this notion.¹³

Recurrence occurs early, typically within the first month after transplantation, and is manifested initially by heavy proteinuria, followed by hypertension and graft dysfunction. Patients with recurrent disease appear more susceptible to acute rejection and acute kidney injury²³ as well as graft loss. Recurrence has been associated with early graft loss in up to 40% to 50% of cases²¹; however, the adoption of plasma exchange appears to have delayed graft loss in many cases and decreased the incidence of overall graft failure (see Fig. 104.2).³

A circulating 50-kD plasma protein that is bound to immunoglobulin appears to cause recurrent FSGS. The protein remains unidentified but is capable of inducing proteinuria when it is injected into rat kidneys.^{24,25} Attempts to use the presence of the circulating “permeability factor” as a guide to the risk of recurrence have not produced a clinically useful test. Plasma exchange or immunoadsorption effectively removes the permeability factor because it is bound to immunoglobulin and as a result provides an effective therapy for many patients who develop recurrent FSGS.^{24,25} Although it has not been subjected to a randomized, controlled, prospective trial, several series have reported disease remission in the majority of patients who receive treatment within 2 weeks of recurrence.^{21,26} Potential for positive publication bias and the absence of randomized clinical trial evidence make prognostic information speculative; however, in the authors' assessment, response rates appear likely to exceed 50% when therapy is commenced within 2 weeks of the onset of clinically recurrent FSGS, with lower response rates anticipated when therapy is delayed. Given that graft survival appears to be significantly prolonged in cases that respond to therapy, a course of therapy is warranted in all cases unless clear

Figure 104.6 Approach to the detection and management of focal and segmental glomerulosclerosis (FSGS) recurrence. ACE, angiotensin-converting enzyme; ACR, albumin/creatinine ratio; ARB, angiotensin receptor blocker; CNI, calcineurin inhibitor. Authors' recommendation based on Davenport.²⁷

contraindications to plasma exchange exist (see Chapter 95). A minority of patients with an incomplete response or relapse after cessation of initial therapy will require repeated or long-term plasma exchange²⁷ or concurrent treatment with secondary agents, such as rituximab or cyclophosphamide.^{26,28} Pretransplantation plasma exchange has not been shown to be of benefit in the prevention of recurrence in the graft. The role of concomitant immunosuppressive therapy, in addition to that required to prevent acute rejection, is unclear, although in the opinion of the authors, it should be considered in cases in which stable remission induction is not achieved by plasma exchange alone. See Figure 104.6 for an approach to the management of recurrent FSGS.

Minimal change disease is a far less frequent cause of ESRD. Recurrence of disease after transplantation has been reported; however, it is difficult to be sure that the underlying disease was not FSGS.

Membranoproliferative Glomerulonephritis

Recurrent MPGN bears major clinical and histologic similarities to the subgroup of patients with CAN who have transplant glomerulopathy, and comprehensive assessment of transplant biopsy specimens (see Fig. 104.4 and compare with Figs. 103.3 to 103.5) as well as accurate diagnosis of the native kidney disease is crucial

in making this distinction (see Fig. 104.3). MPGN is suggested by the presence of crescents on light microscopy, stronger staining for C3, and weaker staining for IgM on immunohistology and by the presence of subendothelial or intramembranous dense deposits on electron microscopy.¹⁴ This distinction has important clinical implications, particularly as a recurrence carries a higher risk of subsequent recurrence should retransplantation be considered.

Membranoproliferative Glomerulonephritis Type I

This disorder appears to be mediated by glomerular deposition of immune complexes, triggered by exposure to endogenous or exogenous (e.g., hepatitis C virus [HCV]) antigens. As the antigens are not necessarily removed by transplantation, recurrence of disease is possible and is seen in 20% to 33% of graft recipients.²⁹ Graft loss has been reported in up to 40% of those with recurrence, and the risk of recurrence in subsequent grafts approaches 80%.³⁰ Significant geographic diversity in the risk of recurrence is evident, largely linked to the prevalence of HCV; much higher rates of graft loss due to recurrence are reported in areas where the majority of patients with MPGN are HCV positive, such as Spain,^{29,31} compared with low HCV prevalence areas, such as Australia.³ Patients receiving HLA-identical grafts appear to be at increased risk of recurrence in some series²⁹ but not in others.³

No form of treatment is proven, and the underlying cause of recurrent MPGN should be considered in each case. Prevention may be effective in HCV-associated MPGN, as interferon-based therapy appears to be effective for virus elimination if it is undertaken while the patient is on maintenance dialysis, and this provides substantial protection from HCV viremia and MPGN recurrence after subsequent transplantation.³¹ By contrast, the use of interferon after transplantation may precipitate acute rejection and should be avoided. Other antivirals, such as ribavirin, are unlikely to be successful as monotherapy. Other forms of MPGN type I have been treated with immunosuppression or plasma exchange with success in single cases.

Dense Deposit Disease (Membranoproliferative Glomerulonephritis Type II)

This disease has been found to recur in 50% to 80% of grafts, typically presenting with proteinuria, hematuria, and slowly progressive loss of kidney function.³² The disease course tends to be slow, and although graft loss due to recurrence is ultimately seen in approximately 20% of cases, this generally occurs beyond the first 10 years after transplantation.^{3,32} Graft loss has been associated with male gender, crescents on biopsy, and heavy proteinuria.³² No effective therapy is known, and although plasma exchange and immunosuppression have been described, these are not warranted in the opinion of the authors, and control of blood pressure and proteinuria with renin-angiotensin blockade is the preferred therapy. Given the emerging role of factor H mutations in dense deposit disease (see Chapter 21), plasma infusion or administration of recombinant factor H may prove useful in the future.

Membranoproliferative Glomerulonephritis Type III

Recurrence of this rare disease has been reported, resulting in graft loss in the longer term.³³

Congenital Nephrotic Syndrome

Congenital nephrotic syndrome of the Finnish type has, in small case series, been reported to recur after transplantation and to cause graft loss; however, it is likely that the mechanism of kidney damage is quite different between primary and recurrent disease. In cases in which the primary disorder is caused by a mutation of the *NPHS1* gene that results in complete absence of nephrin, transplantation causes *de novo* exposure to nephrin in the transplanted kidney. Neoantigen exposure causes antibody development and deposition that damages the slit diaphragm and produces a type of MN with podocyte fusion on electron microscopy and a clinical picture of heavy proteinuria and ultimately graft failure.³⁴ Cyclophosphamide-based rescue therapy may be successful.³⁵

ANCA-Associated Pauci-immune Vasculitis

A pooled analysis of all reported case series examining recurrence of antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis, incorporating 127 patients, has largely clarified the behavior of this group of disorders after transplantation.³⁴ Disease recurrence was detected in 17% of cases after 4 to 89 months of follow-up, with renal involvement demonstrated in approximately 60% of these recurrences and graft losses reported in a minority of these. Clinical parameters were not useful in predicting those patients likely to suffer a relapse after transplantation. Pretransplantation disease course, duration of dialysis,

ANCA titers at time of transplantation and during follow-up, c-ANCA or p-ANCA specificity, disease subtype (Wegener's granulomatosis, microscopic polyangiitis, or renal-limited vasculitis), and donor source had no significant impact on recurrence rate.³⁴

The prevention and management of relapse have not been prospectively examined. In most reports, patients did not receive a transplant until they were in clinical remission; however, successful transplantation in the face of persisting ANCA positivity is well recognized. In the absence of evidence, the authors recommend that clinical remission be maintained for at least 6 months before transplantation to reduce the risk of recurrence and also to avoid the risks associated with transplantation in a debilitated patient, especially if ESRD has occurred soon after presentation with systemic vasculitis. Patients with renal relapses have generally been managed with cyclophosphamide-based regimens as used for renal vasculitis in native kidneys, reported to be successful in inducing a remission in 11 of 16 (69%) cases.³⁴ The negative impact of using cyclophosphamide to treat relapse has not been reported, but it would clearly include a significant increase in the risk of bladder cancer.

Kidney transplantation for ANCA-associated vasculitis is associated with a reduction in the frequency of disease relapse by approximately 50% compared with patients remaining on dialysis, and patient and graft survival after transplantation is similar to that of other transplant recipients.³⁴

Goodpasture's Disease

Histologic recurrence of anti-GBM disease (Goodpasture's disease) is seen in 50% of patients who receive a transplant while circulating anti-GBM antibodies persist but rarely when patients undergo transplantation 6 months or more after the disappearance of anti-GBM antibodies. With delayed transplantation, the rate of clinical recurrence is very low, and since the implementation of this practice in Australia, no grafts were lost after transplantation in 47 cases observed for up to 10 years.³ Rare episodes of recurrence should be treated as for native kidney disease with corticosteroids, cyclophosphamide, and aggressive plasma exchange (see Chapter 23).

Recurrent anti-GBM disease is distinct from *de novo* anti-GBM disease, which is seen in up to 15% of transplant recipients with Alport's syndrome who develop anti-GBM antibodies in response to neoantigen exposure (α chain of type IV collagen) through the transplant.³⁶ This is also discussed further in Chapter 23.

Lupus Nephritis

The reported recurrence rate of lupus nephritis (LN) has varied from 1% to 30%.^{37,38} Recurrence has been reported early (days) and late (years) after transplantation, with a mean time to recurrence of 3.1 years in the largest series reported.³⁹ The clinical and histologic pattern of recurrence is variable, but it is typically more benign in histology and clinical expression than the patient's original disease. Whereas the majority of patients with ESRD caused by lupus have had diffuse proliferative (class III or class IV) disease, mesangial proliferative (class II) disease is the most commonly described lesion after transplantation, followed by class III and membranous (class V).⁴⁰ Duration of dialysis before transplantation and serologic activity do not predict recurrence, and antinuclear antibody titer and complement levels are unreliable markers of disease recurrence. There is no reliable relation-

ship between recurrence of nephritis and activity of extrarenal lupus after transplantation.

The long-term outcome for lupus patients after transplantation is controversial but appears similar to that of the general post-transplantation population.³⁷ Whereas recurrence is an uncommon cause of graft loss within the first 10 years after transplantation, with no cases of graft loss reported from 86 recipients in one registry analysis,³ late graft losses do occur. It is clear that lupus patients, particularly those with a lupus anticoagulant, are at increased risk of thrombotic events after transplantation, including graft thrombosis.³⁷

Management of recurrent LN has not been systematically studied; however, the use of corticosteroids, cyclophosphamide, and plasma exchange has been reported, with variable results.⁴⁰ The impact of MMF, which is effective in management of diffuse proliferative LN in native kidneys, remains to be proven. Anticoagulation during the perioperative and early post-transplantation phases should be considered for those with a history of thrombosis or lupus anticoagulant positivity. Successful retransplantation has been reported after graft loss due to recurrence.³⁹

Thrombotic Microangiopathy and Hemolytic-Uremic Syndrome

The diagnosis of recurrent thrombotic microangiopathy (TMA) or hemolytic-uremic syndrome (HUS) is complicated by the fact that *de novo* HUS is seen in 1% to 5% of kidney transplant recipients, most commonly in association with the use of calcineurin inhibitors (both tacrolimus and cyclosporine carry a similar risk), sirolimus, and OKT3 or with acute vascular rejection. Drug-induced *de novo* HUS is generally observed within 14 days of drug commencement.⁴¹ A meta-analysis that examined 10 reports covering 159 grafts in 127 patients reported recurrence in 28% of cases, and this was strongly associated with a poor outcome; 1-year graft survival was 33% for those with recurrence versus 77% for those free from recurrence ($P < .001$).⁴² Recurrence risk is clearly associated with the type of HUS/TMA. Typical childhood postdiarrheal (D^+) HUS seldom recurs, whereas recurrence of atypical (D^-) HUS is frequent and, particularly in hereditary forms, may be associated with mutation of complement components or complement regulatory factors in up to 80% of cases. In a French pediatric series, atypical (D^-) HUS recurrence was observed in more 50% of cases, and of these, graft loss was seen in 80%.⁴¹ Mutations in complement regulatory proteins I and H are associated with a risk of recurrence of approximately 80%, whereas HUS associated with membrane cofactor protein mutations recurs in only 20%. HUS associated with mutations of factors B and C3 has also been reported to recur after transplantation. Given the variation in risk of recurrence associated with mutations of different complement components, genotypic evaluation before transplantation is advisable in all cases of ESRD caused by atypical (D^-) HUS.⁴³ Recurrence is also associated with an older age at onset, rapid progression of the original disease, earlier transplantation, living related transplantation, and use of calcineurin inhibitors.⁴² Recurrence is generally within the first 6 months after transplantation; however, late recurrences have been reported.⁴² The clinical presentation may be gradual or abrupt, with thrombocytopenia, hemolysis, and progressive renal dysfunction.

Whereas *de novo* disease may respond to withdrawal of the inciting agent, management of recurrent disease is uncertain. The authors recommend withdrawal of any potential causative agent, such as calcineurin inhibitors, and if this is not effective

after 48 hours, a trial of plasma exchange should be initiated with three half-plasma volume exchanges performed on 3 consecutive days using fresh frozen plasma for replacement. As an increased incidence of acute rejection has been reported in patients with recurrence,⁴⁴ inadequate immunosuppression after calcineurin inhibitor withdrawal should be avoided by a temporary increase in the dose of corticosteroids or mycophenolate. In cases of life-threatening thrombocytopenia or hemolysis, hematologic stability may be restored by transplant nephrectomy. When an underlying genetic complement regulatory protein defect is known, specific therapies are emerging, such as combined liver-kidney transplantation for factor H deficiency (see Chapter 28).⁴⁵ The prognosis of recurrent disease is poor. More than 50% of grafts are lost within the first year, and graft survival beyond 5 years is uncommon.⁴² There is no evidence that calcineurin inhibitor avoidance is useful in preventing recurrence.

Scleroderma

An analysis of 86 patients reported to the United Network for Organ Sharing registry after receiving a kidney transplant for scleroderma demonstrated graft survival of 62% at 1 year and 47% at 5 years after transplantation; 24% of recipients died during the 10-year observation period.⁴⁶ The recurrence rate could not be accurately determined; however, recurrence was responsible for graft loss in 21% of cases in which the cause was identified, which is consistent with previously accepted recurrence rates. Risk factors for recurrence were not identified, and cyclosporine use did not appear to affect the recurrence rate.⁴⁶ The effect of transplantation on the extrarenal manifestations of scleroderma has not been well documented. The management of scleroderma after transplantation is unstudied; however, the use of RAS blockade after transplantation to treat hypertension would seem appropriate. Overall, the post-transplantation course of scleroderma appears to be similar to that of LN,⁴⁶ and renal transplantation appears to be an appropriate therapy for those with ESRD.

AMYLOID, LIGHT-CHAIN DISEASE, AND FIBRILLARY AND IMMUNOTACTOID GLOMERULOPATHIES

Amyloidosis

The risk and impact of recurrence for patients who undergo transplantation because of systemic amyloidosis are clearly dependent on its cause. Management of AL amyloid is primarily directed to treatment of the underlying plasma cell dyscrasia, most commonly by high-dose chemotherapy and bone marrow transplantation. AL amyloidosis will recur after transplantation if the malignant disease is not fully controlled but may be susceptible to further chemotherapy.

Secondary (AA) amyloidosis is typically a more insidious disease; renal failure is a relatively frequent complication, and renal transplantation is frequently effective. The risk of recurrence of AA amyloid depends on the ability to eradicate the underlying cause of chronic inflammation. Recurrence is unlikely in AA amyloid due to chronic infection if the infection can be eradicated before transplantation, whereas conditions such as rheumatoid arthritis may persist after transplantation and lead to recurrent amyloid in the graft. Patients with AA amyloid associated with familial Mediterranean fever, which can be managed after transplantation with colchicine, have recurrence in less than

5% of cases at 10 years after transplantation.⁴⁷ A Norwegian series of 62 transplants in patients with AA amyloid, mostly secondary to rheumatic diseases, demonstrated a recurrence rate of 10% at an average of 5 years of follow-up, causing graft loss in two cases only. Overall, patient and graft survival rates were 65% and 62%, respectively, at 5 years, with most losses due to infection.⁴⁸

Light-Chain Nephropathy

Patients with light-chain nephropathy have occasionally received transplants, and recurrence is common; one case series reported recurrence in five of seven patients at a range of 2 to 45 months after transplantation. Those with recurrence developed proteinuria, hypertension, and progressive graft dysfunction. One of seven has enjoyed long-term graft function, and one died soon after transplantation because of myeloma.⁴⁹ Kidney transplantation is therefore generally inadvisable for patients with this disease, unless it is performed in conjunction with bone marrow transplantation as a means of curing the underlying disease.

Fibrillary and Immunotactoid Glomerulopathies

Fibrillary and immunotactoid glomerulopathies are known to recur in approximately 50% of those undergoing transplantation for these diseases. Although early graft loss due to recurrence has been reported, decline in graft function is most commonly slow and does not appear to have an impact on 5-year graft survival rates.⁵⁰

RECURRENCE OF METABOLIC DISEASES AFFECTING THE KIDNEY TRANSPLANT

Diabetes Mellitus

Diabetes mellitus is the most common cause of ESRD in most parts of the world; however, these patients undergo transplantation less commonly than those with GN because of a higher prevalence and severity of cardiovascular comorbidity. Recurrence of diabetic nephropathy is well recognized both histologically and clinically, affecting at least 25% of recipients at an average follow-up of 6 years, with some cases diagnosed within 3 years of transplantation.⁵¹ Histologic and clinical features are similar to those of native kidney diabetic nephropathy. The risk of graft loss due to recurrence has not been well documented but appears to be significantly less than with GN, probably because of the competing risk of death due to cardiovascular disease. New-onset diabetes after transplantation is also common and has been reported to cause nephropathy in the graft in a similar proportion of cases, also commonly manifested within 5 years of transplantation. The extent to which this contributes to graft loss also awaits clarification, although a recent analysis of registry data suggests that the impact on graft failure is insignificant in comparison to the impact on premature death with a functioning graft.⁵

Primary Hyperoxaluria

Primary hyperoxaluria (see Chapter 57) is a rare autosomal recessive disease caused by defective or absent hepatic production of alanine-glyoxylate aminotransferase, resulting in systemic accumulation of calcium oxalate (oxalosis). Kidneys and blood vessels in particular are affected. Kidney transplantation alone is

Figure 104.7 Recurrent primary hyperoxaluria. Light microscopy demonstrates oxalate crystals within the tubular lumen (arrows) with a secondary interstitial inflammatory infiltrate.

frequently complicated by hyperoxaluria and consequent recurrence in the graft and ultimately graft loss (Fig. 104.7). By contrast, combined liver-kidney transplantation corrects the underlying metabolic deficit and permits long-term kidney graft survival. In an analysis of the U.S. Renal Data System that included 190 adults with oxalosis who went on to renal transplantation, 134 patients who received a kidney transplant alone experienced 48% 8-year death-censored graft survival. This was inferior to 56 patients who also received a liver (76%) and inferior to a control group with a primary diagnosis of GN (61%).⁵² Aggressive removal of residual oxalate before transplantation by dialysis and after transplantation by pyridoxine supplementation and maintaining high urine volumes may also decrease the risk of graft damage.

Fabry's Disease

Fabry's disease results from a defect in lysosomal α -galactosidase A enzyme, which results in tissue accumulation of trihexosylceramide, eventually causing ESRD (see Chapter 46). Recurrent Fabry's disease has been documented within the graft; however, graft survival does not appear to be affected. Treatment with recombinant α -galactosidase A, should this become widely available, is likely to reduce the risk of ESRD and also that of recurrence.

RECURRENCE OF VIRUS-ASSOCIATED NEPHROPATHIES AND TUMORS IN THE TRANSPLANTED KIDNEY

Virus-associated kidney diseases may recur after transplantation. Hepatitis B and C virus-associated MPGN and MN are known to recur; however, the risk of this can be substantially decreased by successful antiviral therapy before retransplantation (see Chapter 55).

Retransplantation has been reported in patients experiencing graft loss due to BK virus nephropathy. In the largest series, recurrence was documented in 1 of 10 transplant recipients at an average follow-up of 3 years.⁵³ Measures to decrease the risk of recurrence included delay in retransplantation by an average of 13 months and transplant nephroureterectomy in seven cases. Calcineurin inhibitor-based triple immunosuppressive therapy was used in all cases, and the one case of recurrence experienced stabilization of graft function after a reduction in immuno-

suppression.⁵³ Thus, retransplantation, ideally delayed until BK virus is not detectable in serum by polymerase chain reaction, appears to be safe and effective.

Patients who develop post-transplantation lymphoproliferative disease and incur graft loss due to direct infiltration or rejection after the withdrawal of immunosuppression may safely and successfully undergo retransplantation after a period of recovery. There was no evidence of recurrence reported in one series of five cases.⁵⁴

Outcomes of Renal Transplantation

Titte R. Srinivas, Jesse D. Schold, Herwig-Ulf Meier-Kriesche

Despite the increasing number of people worldwide living with a functioning kidney transplant, the waiting list for kidney transplants continues to grow. A transplant kidney is therefore a relatively scarce resource, making it critical that factors influencing transplant outcomes are well understood.

Data on transplant outcomes are derived from databases maintained by single transplant centers, cooperatives of single centers and industry-sponsored trials, and large multicenter registries. Large databases include the U.S. Renal Data System (USRDS),¹ the Scientific Registry of Transplant Recipients (SRTR),² the United Network for Organ Sharing (UNOS),³ and the Collaborative Transplant Study (CTS); registries are also maintained by Canada, Australia, and New Zealand and the United Kingdom.^{4,5} The USRDS and SRTR reports are based on mandatory reporting of outcomes for almost all transplant recipients in the United States. The CTS reports data submitted on a voluntary basis by participating centers in many countries. The SRTR and USRDS databases through cross-links to other databases contain well-validated data on dates of patient death and return to dialysis. However, the large registries typically lack clinically relevant data, such as immunosuppressive drug dosing, blood pressures, and serum lipids, whereas single-center observational studies and clinical trials frequently provide data on the impact of such variables on graft and patient survival.

“Hard outcomes” for renal allografts include graft and patient survival. “Soft outcomes” used as surrogates for graft survival include serum creatinine, proteinuria, rejection rates, and biopsy-derived pathologic features. Other important measures include days of hospitalization, quality of life, and patient satisfaction indices.

Randomized controlled trials of interventions, such as immunosuppressive regimens, are often impractical for comparison of effects on allograft survival.⁵ It is difficult to design adequately powered trials to demonstrate statistically significant differences in graft or patient survival within the short periods of follow-up, given practical and financial constraints for the sample sizes needed in such trials.

UNDERSTANDING SURVIVAL MODELS

Survival analysis may also be referred to in other contexts as failure time analysis or time to event analysis. The events applicable for outcomes studies in transplantation include graft failure, return to dialysis or retransplantation, patient death, and time to acute rejection.^{6,7}

Most analyses use the Kaplan-Meier method, which yields an *actuarial estimate* of graft survival. The assumptions underlying these models and the relevant terminology are summarized in Figure 105.1. Most national registries report graft survival as

unadjusted or as being *adjusted* for age, gender, and end-stage renal disease (ESRD) diagnosis. This adjustment by multivariate techniques accounts for differences in baseline characteristics that may otherwise confound the results. Another relevant measure is the median graft survival, commonly referred to as the allograft *half-life*. This is distinct from the *conditioned half-life*, which is defined as the median graft survival among those who have already survived the first year after transplantation.⁸ Graft survival may be reported as cumulative graft survival or its reciprocal, cumulative graft loss. When patient death is counted as a graft loss event, the results are reported as *overall graft loss (or survival)*. The most important causes of death with a functioning transplant are cardiovascular disease, infection, and malignant disease; the last two reflect the impact of the immunosuppressed state.² Death with a functioning transplant is an increasingly common cause of late graft loss with more older patients receiving kidney transplants.

Death with a functioning transplant when it is not counted as a graft loss is reported as *death-censored graft loss (survival)*. This allows study of factors affecting graft function independent of factors mediating mortality. An increased risk of mortality will be manifested as increased overall graft loss and relatively preserved death-censored graft loss. As a caveat, estimates of rates of death-censored graft loss may be biased by risk factors affecting both mortality and attrition of graft function, for example, diabetes mellitus and hypertension.

Graft loss is termed early graft loss in the first 12 post-transplantation months and late graft loss after the first 12 months.⁹ Early graft loss is dominated by vascular technical failures, primary nonfunction, recipient death, or severe rejection. After 12 months, the rate of graft loss is lower and remains remarkably stable over time. The dominant causes of late graft loss include chronic rejection and multifactorial interstitial fibrosis and tubular atrophy (IF/TA, formerly designated chronic allograft nephropathy; see Chapter 103),¹⁰ calcineurin inhibitor (CNI) nephrotoxicity, recurrent disease, and patient death. The predominant causes of patient mortality after 12 months are cardiovascular, infectious, and malignant diseases (Fig. 105.2). The principal causes of patient death in the first year are cardiovascular disease and infection (malignant disease is much less common).⁹

SURVIVAL ADVANTAGE FOR TRANSPLANTATION OVER DIALYSIS

Transplantation is accepted as conferring a durable survival benefit over dialysis, despite the inherent selection bias in that a transplant is a viable option only in the fittest dialysis patient.¹¹

Assumptions and Key Features of Kaplan-Meier and Proportional Hazard Models

Survival analysis models *time to the event of interest*.

Not all possible events may have occurred by the end of the observation period; the only information available about some subjects is that they were free of the event of interest at the time of last follow-up (*censoring assumption*).

However, if the probability that a subject is censored is related to the probability of that subject suffering an event (*informative censoring*), then the application of censoring may be inappropriate (*noninformative censoring*).

A common descriptor of the survivorship of a cohort is the *hazard function*, which is commonly interpreted as the event rate at a particular point in time, conditional on surviving to that point in time.

There are different types of survival models that also are based on varying levels of assumptions. Kaplan-Meier plots do not require any distributional assumptions. Cox proportional hazard models do not specify a form for the underlying hazard but assume a proportional multiplicative effect of treatments and are also referred to as a semiparametric model.

Cox regression models can include multiple covariates but assume that the impact of these covariates does not change over time (*proportional hazards assumption*).

Differences in survival between two groups can be compared by using a variety of tests. For Kaplan-Meier plots, log-rank and Wilcoxon tests are most commonly used.

The *relative hazard* describes the ratio of time to outcome given a particular risk factor to time to outcome when the risk factor is not present.

Cox regression (proportional hazard model) is a multivariate method that allows an analysis of the relative contribution of numerous explanatory variables or potential cofounders to the variable of interest, time to event. Cox models assume that the relative hazard between groups does not change with time.

Figure 105.1 Survival analysis for kidney transplantation: assumptions and key features of Kaplan-Meier and proportional hazard models. (Modified from references 6 and 7.)

Common Causes of Kidney Transplant Failure

Death with function	40%–45%
Failure of the transplant kidney	55%–60%
Chronic allograft nephropathy (chronic transplant glomerulopathy; 5%)	30%
Recurrent or <i>de novo</i> disease (including BK virus nephropathy)	10%
Miscellaneous and mixed picture (unknown, multifactorial, end-stage renal disease from medical illness)	10%
Technical and thrombosis	2%
Outright rejection	5%

Figure 105.2 Common causes of kidney transplant failure. (U.S. Renal Data System from reference 9.)

Adjusted Relative Risk of Death After First Cadaveric Transplant

Figure 105.3 Adjusted relative risk of death among 23,275 recipients of a first cadaveric transplant. The reference group was the 46,164 patients on dialysis who were on the waiting list (relative risk 1.0). Values were adjusted for age, sex, race, cause of end-stage renal disease, year of placement on the waiting list, geographic region, and time from first treatment for end-stage renal disease to placement on the waiting list. (U.S. Renal Data System with permission from reference 11.)

The best comparator group is patients who have passed the initial evaluation for transplantation and are on a waiting list but not yet transplanted.

A study using the USRDS database showed that on average, after the first 106 post-transplantation days, the relative risk of death was higher for those patients on the waiting list who continued on dialysis.¹¹ This excess early mortality presumably reflected the medical and surgical risk associated with the transplant procedure *per se*. However, the time to equal risk of mortality observed in this study varied widely between 5 and 673 days after transplantation (Fig. 105.3). With up to 4 years of follow-up, transplantation was associated with a 68% lower risk of death. Transplantation particularly benefited diabetic recipients.¹¹

The salutary effect of transplantation is likely to reflect reduction in cardiovascular mortality by successful transplantation. The better the function of the transplanted kidney, the lower the cardiovascular mortality (Fig. 105.4).¹²

Donor Source and Quality

Transplant kidneys are derived from living related or unrelated donors or deceased donors. Some deceased donor kidneys are retrieved after brain death but before cardiac death; others are retrieved after cardiac death (DCD). DCD kidneys form an increasingly valuable addition to the deceased donor pool. Donors are classified as being expanded criteria donors or standard criteria donors; this may be rather simplistic because there is a continuous spectrum of donor quality that has an impact on graft survival (Fig. 105.5).¹³

PATIENT AND GRAFT SURVIVAL IN KIDNEY TRANSPLANTATION

The data quoted in this section were obtained from the 2006 report of the SRTR for first and subsequent transplants (Fig. 105.6).¹⁴ Living donor transplants have significantly better 1-, 3-,

Figure 105.4 Kidney transplant function and cardiovascular mortality. Worse post-transplantation renal function is associated with higher risk of cardiovascular mortality. (From reference 12.)

Figure 105.5 Deceased donor nomenclature in kidney transplantation.

Deceased Donor Nomenclature in Kidney Transplantation	
Term	Definition
Expanded criteria donors (ECD)	For kidney, any deceased donor older than 60 years; or from a donor older than 50 years with two of the following: a history of hypertension, a terminal serum creatinine >1.5 mg/dl (132μmol/l), or death resulting from a cerebrovascular accident (stroke)
Donation after cardiac death (DCD)	Donation of any organ from a patient whose heart has irreversibly stopped beating; includes donors who also qualify as ECD under the kidney definition above
Standard criteria donors (SCD)	For kidney, a deceased donor who is neither ECD nor DCD. These donors have fewer risks associated with graft failure.

and 5-year unadjusted graft survival compared with non-extended criteria deceased donor transplants, which in turn have graft survival superior to that of extended criteria deceased donor transplants.¹⁴

Patient survival data are higher than graft survival figures as most patients with failed grafts return to dialysis. Again, living donor transplantation has superior unadjusted patient survival rates at 1, 3, and 5 years compared with non-extended criteria deceased donor transplants, which in turn have graft survival superior to that of extended criteria deceased donor transplants.¹⁴

One-year graft survival has improved steadily during the past 25 years (Fig. 105.7).¹⁵ First transplants consistently have better one-year survival than subsequent grafts, probably reflecting a superior immunologic risk profile.

LONG-TERM OUTCOMES IN RENAL TRANSPLANTATION

Graft Survival

There has been a steady improvement in long-term graft survival. This largely represents improving graft survival in higher risk patients, such as those undergoing retransplantation.¹⁵ When first deceased donor transplants alone are assessed, recent improvements are less impressive.¹⁶ Substantial improvements in graft survival have been reported by use of projected half-lives,¹⁵ but these should be interpreted with caution as eventual actual outcomes may differ from actuarial estimates¹⁶ Although there have been significant recent decreases in acute rejection rates during the first 2 years after transplantation,¹⁶ this

Figure 105.6 Impact of donor source on graft survival. The 1-, 3-, and 5-year unadjusted graft survival by donor source. ECD, expanded criteria donor. (Modified from the 2006 SRTR Annual Report, reference 14.)

has not translated into improved long-term graft survival; indeed, death-censored graft survival has worsened. Moreover, in a greater proportion of acute rejection episodes, renal function did not return after treatment to pre-rejection baseline values, and this was associated with an incremental increase in the relative hazard for death-censored graft survival.^{16,17} It may be that the more potent immunosuppression in current use allows the expression of only more severe episodes of acute rejection, so these episodes have less good outcomes. At the same time as there has been the use of increasingly intensive immunosuppression, there has also been an increasing recipient comorbidity, a decreasing donor quality (increasing numbers of older donors), and a disturbing rise in opportunistic infections such as polyomavirus (BK virus).

Beyond the first post-transplantation year, the principal causes of graft loss are patient death and multifactorial progressive fibrosis of the allograft, until recently termed chronic allograft nephropathy and now designated interstitial fibrosis/tubular atrophy (IF/TA), which is discussed further in Chapter 103.

Patient Survival

The predominant cause of death more than 1 year after transplantation remains cardiovascular disease, followed by infection and malignant disease. This is likely to reflect varying contributions from age, comorbidity, burden of immunosuppression, progressive allograft dysfunction, and side effects of immunosuppressive agents.

FACTORS AFFECTING RENAL ALLOGRAFT SURVIVAL

These can be considered as donor factors, recipient factors, or donor-recipient interactions.¹⁸ From the point of view of clinical management and therapeutic interventions, another convenient way of discussing these factors is as alloimmune or non-alloimmune factors.

Figure 105.7 Kaplan-Meier overall graft survival by year of transplant: first deceased donor transplants, 1988-1995. The actuarial graft survival curves for each year from 1988 to 1995 are virtually superimposed with no significant difference in graft survival. Graft half-life varies from 7.5 to 8 years during the same period. (From reference 6.)

Donor Factors

The quality of the kidney immediately before transplantation has a major impact on long-term graft function.

Deceased Versus Living Donor

Donor source is one of the most important predictors of short- and long-term graft outcomes. In general, living donor grafts are associated with outcomes superior to those of deceased donor grafts. Not only does a living donor kidney contribute to superior long-term graft survival, it is also associated with a recipient survival benefit that is not fully understood. The advantage of living donor kidneys holds equally true for spousal and unrelated donors and appears to be in large part nonimmunologically mediated (at least non-HLA mediated).^{19,20}

The better outcomes with living donors probably reflect several factors: the higher kidney quality provided by healthy living donors, the absence of brain death, the general benefits of elective as opposed to urgent surgery, the avoidance of ischemia-reperfusion injury, the higher nephron mass transplanted, and the effects of a shorter waiting time. The living donor transplant can be timed in such a way that the recipient is as fit as possible at the time of transplantation.²⁰ There may also be benefit attributable to better social support and emotional state and a greater sense of obligation to maintain medical compliance. However, in recent years, the age of living donors and recipients has continued to increase, both of which may have a negative impact on transplant outcomes in the future.

Donor Age

Deceased donor and living donor grafts from those older than 50 years, and particularly older than 65 years, have poorer outcomes. These results are thought to reflect a higher incidence of delayed graft function and of “nephron underdosing.” Grafts from older donors have fewer functioning nephrons because of the involuntary changes associated with the aging process and the age-related accumulation of hypertension and atherosclerosis. However, because of the organ donor shortage relative to the growing wait list, more organs from elderly donors are being used. The older the donor kidney (>18 years), the shorter the expected graft life.²¹ This effect persists after correction for recipient characteristics that could produce similar effects. The older kidney has limited functional reserve to adapt to a range of insults. It has also been hypothesized that the older kidney may be on a path to programmed senescence after transplantation.²² The effects of donor age interact with those of recipient age (see later).

Deceased donor age younger than 5 years is also associated with poorer outcomes, which probably reflects higher rates of technical complications and possibly nephron underdosing. Transplantation of pediatric kidneys *en bloc* (in which the graft consists of both kidneys with a segment of aorta and inferior vena cava) from donors aged 0 to 5 years has been associated with excellent graft survival.²³

Cold Ischemia Time

Prolonged cold ischemia times are associated with incrementally higher risk of delayed graft function and poorer allograft survival, particularly when cold ischemia times exceed 24 hours (also see discussion on delayed graft function).^{19,24}

Donor Nephron Mass

An imbalance between the metabolic/excretory demands of the recipient and the functional transplant mass has been postulated to play a causative role in the development and progression of chronic transplant dysfunction. Nephron underdosing is a possible consequence of perioperative ischemic damage and postoperative nephrotoxic drugs, or it may be an inherent consequence of a size or gender mismatch between donor kidney and recipient. It may lead to hyperfiltration, progressive glomerulosclerosis, and eventual graft failure. Kidneys from small donors transplanted into recipients of large body size would therefore have the highest risk of this problem.²⁵ There is limited support for this hypothesis from animal studies and retrospective human studies; in one relatively small single-center study, higher transplant kidney volumes in living donor transplantation correlated with better graft function.²⁶ There are no prospective studies of donor pairs with optimal matching of kidney size to recipient body size that might clarify this issue.

Donor Race

In the United States, the survival of deceased donor grafts obtained from African Americans is poorer than that of grafts from Caucasians. The reasons for this are unclear. It has been attributed to nephron underdosing, but it remains controversial whether African Americans have a decreased number of nephrons compared with Caucasians.²⁷

Donor Gender

There is evidence that grafts from deceased female donors have slightly poorer survival, particularly in male recipients.²⁸ This probably reflects nephron underdosing. It is controversial

whether there may also be a difference in the antigenic repertoire between female and male kidneys that could influence outcome. Because the donor gender effect was not observed in the pre-CNI era, the effect may reflect differential susceptibility of the female donor kidney to CNI toxicity.²⁹

Expanded Criteria Donors

As the discrepancy between the number of patients awaiting kidney transplantation and the number of available organs increases, there is increasing use of expanded criteria donor (ECD) kidneys. ECD kidneys (see Fig. 105.5) have poorer survival than ideal deceased donor kidneys, with an estimated adjusted relative risk of failure greater than 1.7.³⁰ Factors mediating this effect include reduced baseline glomerular filtration rate of ECD kidneys and their preferential use for older recipients who have higher rates of post-transplantation death. In a study of 122,175 patients on the UNOS transplant waiting list between 1992 and 1997, mean ECD recipient survival was 5 years longer than for patients remaining on the waiting list, whereas the recipient of an ideal deceased donor kidney accrued a 13-year survival benefit. Diabetics obtained the greatest proportional survival benefit, and those with hypertensive renal disease incurred the greatest absolute gain in life-years.³¹

In the United States, UNOS has implemented policies that allow consenting patients to opt for both an ECD kidney and an “ideal” kidney. Those patients who decline listing for an ECD kidney could potentially incur the increased mortality associated with increased waiting time on dialysis. It is conceivable that the younger nondiabetic patient could wait longer on the list than an older diabetic recipient, who would gain the mortality benefit conferred by transplantation.³² This survival benefit from the ECD transplant can be expected to be proportionately greater in regions with historically higher waiting times.³¹

With DCD kidneys, rates of delayed graft function and primary nonfunction are higher than with standard donors.³³ There is accumulating evidence, however, that long-term graft survival with DCD donors is similar to that with heart-beating deceased donors, although this probably reflects careful selection criteria.³⁴

Recipient Factors

Recipient Age

In general, graft survival rates are poorer in those younger than 17 years and older than 65 years.¹ In the young, technical causes of graft loss, such as vessel thrombosis, aggressive rejection, and noncompliance with immunologic graft loss, are relatively more common. Conversely, death with a functioning graft is relatively rare in the young. In most developed countries, the mean age of the incident and prevalent ESRD population is increasing. Many of these patients have significant comorbidities, particularly cardiovascular disease and type 2 diabetes mellitus. Despite this, age *per se* is no longer regarded as a contraindication to transplantation, which still confers a survival advantage in the carefully selected elderly ESRD recipient.¹¹ It is critical to consider the effect of increasing waiting times on mortality in older patients with ESRD and their suitability for transplantation by the time they are actually offered a transplant. Recent SRTR data show that more than half of patients older than 60 years on the waiting list are expected to die before receiving a renal transplant.³⁵ This underscores the importance of stratifying transplant options for those on the waiting list based on age and comorbidity.

Whereas acute rejection is relatively infrequent in the elderly, there is less chance of a return to baseline function after treatment of an acute rejection episode. Death with a functioning graft is more common with increasing recipient age; however, death-censored graft loss also worsens with increasing age. Recipients aged 50 to 64 years accrue a 29% higher relative risk of graft loss compared with those aged 18 to 49 years, whereas those 65 years or older have a 67% higher relative risk for graft loss.³⁶ This effect of increasing age is independent of traditional determinants of graft survival, such as delayed graft function and acute rejection, and is independent of the immunosuppressive regimen employed. Increasing donor and recipient age is an independent risk factor for graft survival³⁷; the best graft survival is obtained when a kidney from a young donor is transplanted into a young recipient, and the worst graft survival is obtained when kidneys from older donors are transplanted into older donors. The combination of advanced donor and recipient age may have a synergistic detrimental impact on graft survival, perhaps because of the dynamic interplay of an intrinsically senescent kidney transplanted into a senescent biologic milieu.

Death rates due to infection increase linearly with increasing recipient age in those on the transplant waiting list, and in the transplanted elderly patient, infectious mortality rises exponentially.³⁸ Overall mortality and cardiovascular mortality rise with increasing age, but the magnitude of this increased mortality is not greater in transplanted patients compared with those on the waiting list³⁸; indeed, cardiovascular mortality is halved with successful transplantation in the elderly.³⁸ Death due to malignancy is also increased in elderly transplanted patients, perhaps reflecting the additive effects of pharmacologic immunosuppression to natural immune senescence. As yet, there are no reliable methods to measure delivery of effective immunosuppression that can assist further analysis of this issue.

Recipient Race

From the early days of transplantation in the United States, African American patients had inferior graft and patient survival rates. Proposed explanations have included heightened rejection risk, differing HLA polymorphisms compared with the predominantly Caucasian donor pool, differing pharmacokinetics of immunosuppressants, hypertension, noncompliance, and socioeconomic status. However, the difference between African Americans and Caucasians is becoming narrower with newer immunosuppressive regimens.^{39,40} Despite the need for increasing immunosuppression to maintain freedom from acute rejection, African American transplant patients are at decreased risk for death due to infection, which may allow increased immunosuppression to be delivered relatively safely and possibly obviate some of the racial differences in graft survival that were seen in the past. Outcomes after living donor transplants are superior to those of deceased donor transplants in African Americans,⁴¹ but living donation is relatively underused in African Americans and represents a potential target for intervention to improve transplant outcomes.

Socioeconomic factors associated with inability to pay for transplant medications (an issue in the United States and other countries in which universal health coverage does not exist), poorer access to high-quality medical care, and noncompliance may also play a role in mediating the interaction between race and outcomes. Interestingly, an analysis of the United Kingdom national database, a country in which there is universal health coverage, showed that graft survival was inferior in blacks compared with whites or Asians.⁴² An Australian study suggested that

inferior outcomes with transplantation in aboriginals may reflect a significant contribution of socioeconomic factors and differential access to care rather than a direct and exclusive contribution of race.⁴³

Recipient Gender

SRTR data consistently demonstrate better graft survival in male recipients compared with female recipients of living donor kidneys.⁴⁴ An important difference is the higher degree of sensitization of female recipients to HLA antigens and possibly non-HLA antigens due to pregnancy and transfusions (which may be required for menstrual and pregnancy-related blood loss). Female recipients are at greater risk for acute rejection but show lower rates of progressive attrition of graft function.⁴⁵

Recipient Sensitization Before and After Transplantation

Patients who are broadly sensitized (panel reactive antibody status >50%) at the time of transplantation have poorer early and late graft survival compared with nonsensitized recipients.¹⁹ This decrement in early graft survival is mainly related to increased delayed graft function and acute rejection. Patients who are highly sensitized (most commonly as a result of previous transplants, pregnancy, and previous blood transfusions) are often given more intensive immunosuppression to reduce the risk of rejection, but this also exposes them to infectious and neoplastic risk. The donor-specific alloimmune response is a significant contributor to chronic transplant dysfunction and ultimately graft loss.⁴⁶ Although conditioning regimens incorporating plasma exchange and depleting antibodies or intravenous immune globulin can permit transplantation of highly sensitized individuals, the long-term outcomes of these transplants are still uncertain.⁴⁷

Acute Rejection

Acute rejection remains the single greatest risk factor for chronic rejection and graft loss. Whereas acute rejection rates are decreasing, the association of acute rejection and chronic graft failure is increasing during the last 10 years.⁴⁸ The histologic grade of rejection, severity of renal functional impairment at the time of diagnosed rejection, timing of rejection episode, and completeness of response to antirejection treatment all have prognostic significance. Acute rejection episodes with return of allograft function to pre-rejection baseline levels are, however, associated with little impact on long-term allograft survival. Humoral rejection is typically more difficult to reverse and prejudices long-term graft survival to a greater extent than cell-mediated rejections do.¹⁹

Recipient Hepatitis C and Hepatitis B Positivity

Recipients who are hepatitis C virus (HCV) antibody positive at the time of transplantation have graft and patient survival inferior to that of those who are HCV negative. Higher mortality rates in this population are attributed mainly to infection and worsening liver disease.⁴⁹ Despite these limitations, transplantation of selected HCV-positive patients confers a survival benefit over remaining on the waiting list.^{50,51}

The adverse effects of hepatitis B virus (HBV) surface antigen positivity on post-transplantation outcomes are much less pronounced in recent years, reflecting in part the availability of effective anti-HBV therapies.

Recipient Compliance

Poor compliance with the immunosuppressive regimen is known to increase the risk of acute rejection, particularly late acute

rejection, and chronic transplant dysfunction. The exact magnitude of this problem is difficult to define. In a study of patients followed up to 5 years after transplantation, almost a quarter of the patients were identified as being noncompliant on the basis of direct questioning about missing medication doses, and this was associated with a large increase in risk of late acute rejection and poorer graft function.⁵²

Obesity

Obesity (body mass index [BMI] >30 kg/m²) constitutes an important risk factor for cardiovascular disease, hypertension, and diabetes mellitus in the general population. The effects of obesity on long-term graft and patient survival were examined in a study of 51,927 patients reported to the USRDS between 1988 and 1997.⁵³ There was an increased mortality at both low and high extremes of BMI.⁵³ This U-shaped relationship resembles that seen in the general population and also described the relationship between obesity and cardiovascular and infectious mortality. Furthermore, increasing BMI was associated with worsening death-censored graft survival.⁵⁴

Transplantation does confer a survival advantage for the obese dialysis patient. This survival advantage holds true for both living and deceased donor transplantation.⁵⁵ However, weight loss among renal transplant candidates before the procedure did not have an impact on transplant outcomes in a retrospective study.⁵⁶

Recipient Hypertension

Increasingly severe post-transplantation hypertension is associated with increasing risk of graft loss, and control of hypertension is associated with improved graft survival.⁵⁷ Unfortunately, there are only retrospective data that by themselves cannot establish a causal relationship between hypertension and graft loss. Based on extrapolations from studies in nontransplant populations, optimal treatment of hypertension (see Chapter 102) is a reasonable goal to minimize progression of renal dysfunction and the extrarenal complications associated with hypertension.

Recipient Dyslipidemia

Arteriolar fibrointimal hyperplasia is associated with chronic progressive attrition of graft function; this vascular lesion is morphologically reminiscent of atherosclerosis. In a small study, statin treatment was associated with better histologic appearances and better graft function at 1 year. Like treatment of hypertension, the use of lipid-lowering treatment after transplantation is based on evidence that largely represents extension of experiences from nontransplant populations. The treatment of dyslipidemia in transplant recipients is discussed in Chapter 102.

Recurrence of Primary Disease

Determining the incidence and prevalence of recurrent or *de novo* renal disease is not straightforward. In one of the best performed studies of transplant recipients whose cause of ESRD was glomerulonephritis, the cumulative incidence of graft loss at 10 years was 8.4%. In that population, recurrence of glomerulonephritis was the most important cause of graft loss, after chronic rejection and death.⁵⁸ It is likely that as graft survival improves with decreasing acute rejection rates, recurrent or *de novo* disease will become a more important cause of late graft loss, especially given the current trend toward minimizing maintenance immunosuppression. Recurrent disease in renal allografts is discussed further in Chapter 104.

Proteinuria

The degree of proteinuria correlates with poorer renal outcome in both native and transplant kidney disease.⁵⁹ Proteinuria may simply be a marker of renal damage, but there is speculation that proteinuria *per se* may accelerate graft loss in addition to other pathogenetic factors. Increasing evidence points to a link between humoral factors that mediate alloimmune glomerular damage leading to proteinuria. Sirolimus-based regimens have been implicated as a cause of proteinuria. CNI-based regimens may be associated with less proteinuria because of their effects on glomerular hemodynamics or superior immunologic protection. The role of angiotensin-converting enzyme inhibitors and angiotensin receptor blockers in slowing the progression of proteinuric renal diseases is discussed in Chapter 76.

Donor-Recipient Factors

Delayed Graft Function

Delayed graft function (DGF) is defined as failure of the renal transplant to function immediately, with the need for dialysis in the first post-transplantation week. DGF affects approximately 20% of deceased donor transplants. Slow graft function (SGF) is defined as serum creatinine concentration above 3.0 mg/dl (264 μ mol/l) at 5 days after transplantation without requiring dialysis within 1 week of transplantation.⁶⁰ The main risk factors for DGF that are identifiable in the clinical setting include donor age or comorbidity, cold ischemia time, and warm ischemia time. DGF and SGF are likely to reflect the dynamic interplay of the status of the donor kidney (advanced donor age, donor history of hypertension) with peritransplantation injury (e.g., ischemia-reperfusion as a consequence of agonal events or during procurement followed by reperfusion) or cold preservation injury.⁶⁰ Warm ischemia time is also an important risk factor, although its exact contributions to the pathogenesis and maintenance of DGF are difficult to assess because of inaccurate reporting. Early single-center reports suggested that the negative impact of DGF on graft survival could be explained in part by a high incidence of acute rejection in cases with DGF.⁶¹ In analyses of USRDS and UNOS data, DGF was independently associated with reduced short- and long-term graft survival.^{62,63} In a small single-center study, DGF was associated with inferior renal function at 1 year.⁶⁴ ECD kidneys and DCD kidneys are more susceptible to DGF. Increasing cold ischemia time is associated with increased likelihood of DGF with DCD kidneys. Pulsatile machine perfusion of allografts (compared with static cold preservation) has been associated with fewer discards of ECD organs, lower DGF rates, and slight improvement in death-censored graft survival.⁶⁵ In a randomized clinical trial comparing machine perfusion with static cold preservation, machine perfusion was associated with a lower incidence of DGF, faster fall in serum creatinine concentration after transplantation, decreased duration of DGF, and better allograft survival at 1 year after transplantation.⁶⁶

DGF and the use of pulsatile perfusion will continue to be of major clinical importance and will likely gain additional prominence with the larger numbers of ECD and DCD transplants that are now being performed.

HLA Matching

Better HLA matching still translates to superior graft survival, and this is the justification for the operation of national and international sharing systems for zero-mismatched renal kidneys, even though this practice prolongs cold ischemia times and increases DGF rate. However, with improved contemporary

Figure 105.8 Advantage of preemptive transplantation. Preemptive transplants confer a survival advantage over transplants performed in patients who receive dialysis treatment before transplantation. Increasing pre-transplantation dialysis time translates to progressive decline in allograft survival. (From reference 69.)

immunosuppression, HLA matching has taken on less significance; for example, excellent graft survival has been noted in living donor transplants with use of unrelated donors, in which HLA mismatch is more the rule than the exception.²⁰

Nevertheless, registry data confirm that the fewer HLA mismatches, the better the long-term graft survival, especially for donor-recipient pairs with zero mismatches.⁶⁷ The effect of HLA mismatches on graft survival persists after correction for acute rejection in multivariate analysis. Some studies have found a particularly negative effect of mismatch at the DR locus.⁶⁸ This relationship of HLA matching and long-term graft survival is a line of evidence for an immunologic element in IF/TA.⁴⁶ The effect of HLA matching is much less pronounced in living donor recipients. Recent analyses do suggest, however, that the better the HLA match, the lesser the sensitizing effect of graft loss. The overall body of evidence suggests that HLA matching continues to be an important determinant of long-term graft survival.

Waiting Time and Preemptive Transplantation

An analysis of USRDS data shows that a longer waiting time on dialysis is a significant risk factor for both death-censored graft survival and patient death with functioning graft after renal transplantation. Relative to preemptive transplantation, increasing waiting times incrementally increased both mortality risk and risk for death-censored graft survival after transplantation.⁶⁹

In a retrospective cohort study of 8481 patients, preemptive transplantation was associated with a 52% reduction in the relative hazard for graft failure in the first year after transplantation, 82% in the second year, and 86% in the subsequent year compared with transplantation occurring after the start of dialysis.⁷⁰ Increasing duration of dialysis before transplantation significantly increased the risk for acute rejection within the first 6 months after transplantation.⁷⁰ Paired kidney studies can minimize the confounding effect of donor-related factors; in a paired kidney study involving 2405 pairs of kidneys, each kidney of each

pair was transplanted into a recipient with differing times on ESRD.⁷¹ Six antigen-matched kidneys were excluded from this study as a disproportionate number of these kidneys, through a national sharing program in the United States, were transplanted preemptively. Five-year and 10-year unadjusted graft survival and death-censored graft survival were significantly inferior in those subjects with more than 24 months of dialysis time versus those who incurred less than 6 months on dialysis (see Fig. 105.8).⁶⁹ These effects remained significant after adjustment for multiple factors that influence waiting time, such as high panel reactive antibody, advanced recipient age, and race. Part of the advantage of living donor compared with deceased donor transplantation may be explained by the effect of waiting time; a recipient of a deceased donor kidney with an ESRD time of less than 6 months may be expected to obtain graft survival roughly equivalent to that of living donor transplant recipients who wait for their transplant on dialysis for more than 2 years.⁷¹

The exact mechanisms for the benefits of preemptive transplantation are not clear, but alloreactivity is higher with increasing waiting time, an effect more pronounced in African Americans.⁷²

The effect of time on dialysis is potentially modifiable in clinical practice. All patients with ESRD should be referred for transplantation in a timely manner, suitable candidates so identified should be listed as soon as possible, and preemptive transplantation before the start of dialysis should be the ideal goal.

Center Effect

Transplant outcomes vary widely between centers. This may reflect varying clinical expertise. However, mortality on the waiting list is the single biggest correlate of mortality after transplantation.⁷³ It is thus possible that centers with low waiting list mortality, either through selective listing of candidates or through other socioeconomic or geographic factors, may have lower post-transplantation mortality. It has been shown that

centers with longest waiting times also have lower graft survival rates. Past performance and donor quality also significantly affect survival and are independent of center size. Center effects may contribute up to a 4-year difference in life expectancy. In the United States, centers with characteristics associated with good outcomes were distributed more or less uniformly across the country.⁷⁴

Year of Transplant

As noted previously, long-term graft survival has not improved to the extent that might be expected on the basis of progressive reductions in acute rejection rates over the same time period.¹⁷ However, it is slowly increasing, particularly among recipients of deceased donor kidneys. Factors influencing this gain in transplant survival have been attributed to varying contributions of more effective but not more toxic immunosuppressive regimens, better pretransplantation and post-transplantation general medical care, and more effective prevention and treatment of opportunistic infections (particularly cytomegalovirus infection).

Immunosuppressive Regimens

Choice of immunosuppressive regimen has significant effects on both patient and graft survival. The currently used regimens and the evidence supporting the clinician's choice are discussed in Chapter 100.

APPLYING OUTCOMES DATA IN PRACTICE

The clinician must use outcomes data derived from clinical trials or large observational studies to inform the care of individual patients. This is not straightforward; observational studies can only show associations, do not prove cause and effect, and do not necessarily imply that effects noted in aggregated studies translate automatically into expected outcomes in individual patients. The clinician should judiciously use data from both prospective and retrospective studies in formulating the care of individual patients. However, the outcomes data discussed in this chapter lead to some broad principles for clinical practice.

Minimization of waiting time on dialysis or avoidance of dialysis altogether with preemptive transplantation is associated with the best outcomes. The best practice that can help optimize transplant outcomes is therefore early referral for transplantation and early identification of suitable living donors.

In the older recipient, careful attention must be directed to functional status, comorbidity, social support, and rehabilitation in the evaluation process, if the survival benefit of transplantation is to be maximized. Given the excess mortality of older people on the waiting list, identification of suitable living donors and consideration of methods to minimize waiting time, such as selective listing for ECD transplants and dual marginal kidneys, may be options to accrue the survival advantage of transplantation. The challenge is to balance equity, justice, and access so that the elderly transplant recipient receives an organ whose expected survival is optimal for the expected life span of the candidate.

Living donation should be maximized because it is associated with better transplant outcomes than with deceased donors, and this benefit is particularly prominent among some racial groups, including African Americans, who have otherwise inferior outcome with deceased donor transplantation than Caucasians do.

Other factors with major influence in graft and patient outcome are discussed elsewhere, including the choice of immunosuppressive regimen (Chapter 100) and maintenance of cardiovascular health in the transplant recipient (Chapter 102).

Pancreas and Islet Transplantation

Jonathan S. Fisher, M. Reza Mirbolooki, Jonathan R.T. Lakey, R. Paul Robertson, Christopher L. Marsh

Pancreas transplants are performed for the amelioration of insulin-requiring diabetes. Initially, pancreas transplants were performed only in those diabetic patients with chronic kidney disease who needed kidney transplants; these patients underwent simultaneous pancreas-kidney transplantation (SPK). Today, pancreas transplantation alone (PTA) or pancreas transplantation after living related or unrelated kidney transplantation (PAK) is increasingly common. SPK accounted for 67% of all pancreas transplants in 2006 (Fig. 106.1). The 2007 Annual Report of the Organ Procurement and Transplantation Network (OPTN) and the Scientific Registry of Transplant Recipients (SRTR) reveals that the number of pancreata recovered in the United States for 2006 increased by 53% compared with 1997, and there were approximately 4000 people in the United States waiting for pancreas transplants at the end of 2006.¹ Interestingly, there have been recent downward trends in numbers of patients registered for pancreas transplants. New SPK registrations rose from 1412 in 1997 to a high of 2007 in 2000 and declined to 1671 in 2006. Some of this reduction may be due to an increase in the number of patients receiving islet cell transplants. The relative roles of pancreas and islet cell transplantation remain controversial.

PATIENT SELECTION CRITERIA FOR PANCREAS OR ISLET TRANSPLANTATION

Indications for Transplantation

Indications for pancreas or islet transplantation include (1) insulin-dependent diabetes with associated diabetic complications (nephropathy, neuropathy, and retinopathy) and (2) diabetes with episodes of hypoglycemic unawareness.

A number of factors influence the choice between pancreas transplant and islet transplant. Because giving sufficient islets remains a limiting factor, islet transplants are more appropriate for patients with smaller insulin requirements, typically slender women. Larger patients (usually with higher insulin requirements) are more reliably served with whole-organ pancreas transplants. Islet transplantation is performed by a radiographic procedure and therefore is better suited for patients who cannot tolerate the surgical stress of whole-organ transplantation, such as older patients with severe coronary artery disease.

Pancreas or islet transplantations are not routinely performed for type 2 diabetes mellitus because the defect in type 2 diabetes is insulin resistance, not insulin deficiency. There may be a role for pancreas transplantation in type 2 diabetic patients who develop islet failure after years of insulin resistance.

Most of the pancreata for transplantation come from deceased donors. However, one approach to increasing the donor supply has involved living donor laparoscopic distal pancreatectomy with or without simultaneous laparoscopic nephrectomy.²

Should living kidney donor recipients be offered a PAK transplant? An analysis of the United Network for Organ Sharing (UNOS) database revealed no difference in survival of SPK recipients and living kidney donor recipients at up to 8 years of follow-up.³ However, a European study showed an improved 10-year patient survival (83% in SPK versus 70% in kidney transplants alone) and noted a significantly lower progression of macrovascular disease (cerebrovascular, coronary, and peripheral vascular) with SPK transplants.⁴ Therefore, the two-stage approach of PAK after a living donor kidney transplant should perhaps be offered to patients who have a living kidney donor and in whom the cardiovascular risk of the extended procedure required for SPK is considered too great.

The role of PTA transplants in those with preserved renal function has recently been questioned. A single-center study of 131 PTA recipients revealed that PTA is an independent risk factor for the development of renal failure, presumably because of the nephrotoxicity of long-term immunosuppression.⁵ An analysis of the UNOS database demonstrated worse survival for those with diabetes and preserved kidney function receiving a PTA than for those who remained on the waiting list and received conventional therapy.⁶ The recent SRTR data reveal 1-year patient survival rates similar for PAK, SPK, and PTA recipients (ranging from 95% to 97%). However, the 10-year patient survival rate was lowest for PAK recipients at 64% and similar for SPK and PTA recipients with rates of 70% and 71%. SPK transplants experienced the best pancreas graft survival rates, 86% at 1 year and 54% at 10 years. Graft survival rates for PAK and PTA recipients were similar to one another, with 1-year rates of 79% and 80%, respectively, and 10-year rates of 29% and 27%, respectively (Fig. 106.2).¹ Further close study is warranted, keeping in mind that a prospective, randomized trial of pancreas transplantation versus conservative therapy is not practical.

Medical Evaluation

The medical evaluation for the prospective pancreas transplant candidate is similar to that of the kidney-only recipient (see Chapter 98), although the cardiac workup is more extensive. The best candidates for transplantation are younger than 50 years and have a limited number of major complications of diabetes, such as hypoglycemic unawareness or diabetic neuropathy. Additional

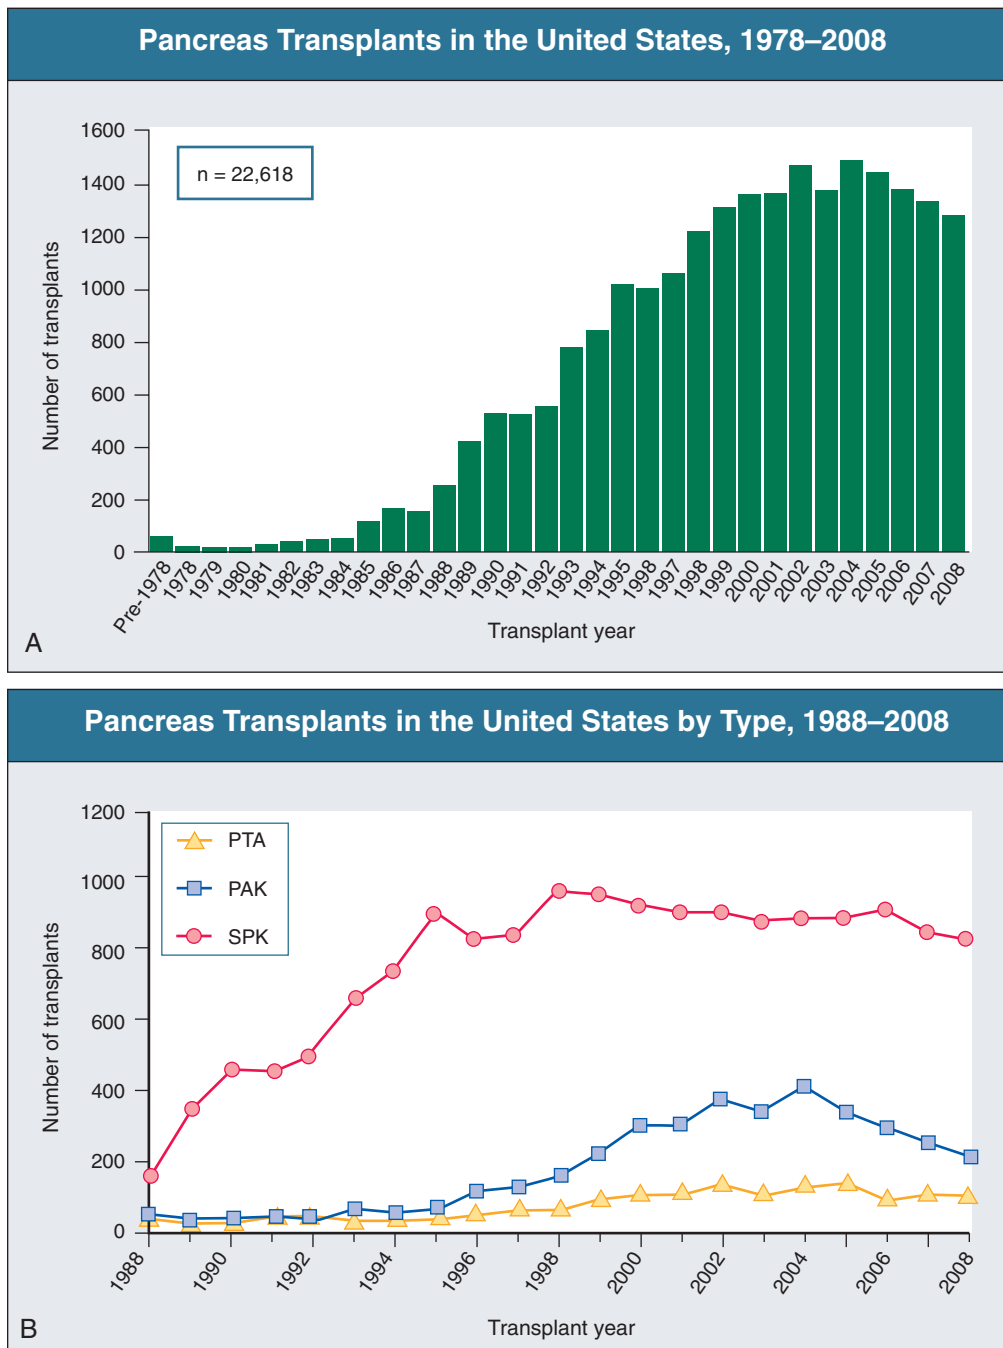

Figure 106.1 Pancreas transplantation. **A**, Number of recipients living in the United States with a functioning pancreas transplant at end of year, 1978–2008. **B**, Pancreas transplants by type in the United States, 1988–2008. PTA, pancreas transplantation alone; PAK, pancreas transplantation after living related or unrelated kidney transplantation; SPK, simultaneous pancreas-kidney transplantation. (From reference 7.)

complications, such as vascular disease, orthostatic hypotension, and severe gastroparesis, put patients at higher risk of post-transplantation complications, but none of these factors by themselves exclude a patient from transplantation. Cardiovascular status is the primary deciding factor for transplantation eligibility because the surgery, infections, risk of thrombotic complications, and, until recently, rejection are more severe in the pancreas transplant recipient, demanding that the cardiovascular system be strong enough to withstand multiple prolonged, hemodynamically stressful events. All patients require noninvasive cardiac stress evaluation because of the limited exercise capabilities of many patients. Cardiac catheterization is performed on the basis of the results of noninvasive testing or performed first

for high-risk patients, typically those older than 45 years, those with diabetes duration of more than 25 years, smokers of more than 5 pack-years, and those with an abnormal electrocardiogram. Peripheral vascular disease is evaluated by clinical examination and by arterial duplex ultrasound. Patients with limb-threatening ischemia are typically poor pancreas transplant candidates. The medical evaluation for islet transplantation is similar to that for pancreas transplantation, but exclusion criteria are fewer because of lower surgical and inflammatory risks.

The last criteria for transplantation are that the donor and recipient match for ABO blood group and that the recipient sera are crossmatch negative against donor T cells by either the standard antiglobulin or flow cytometry crossmatch.

PANCREAS TRANSPLANTATION

Patient and Graft Survival

Pancreas graft survival rates have increased as a result of improved surgical techniques, improvement in the composition of the preservation fluid, and more effective immunosuppressive regimens, despite an increasing proportion of high-risk patients.

The most commonly used cold storage solution is the University of Wisconsin (UW) solution, which has increased early pancreas graft function and reduced the occurrence of preservation pancreatitis. A second cold storage solution, histidine-tryptophan-ketoglutarate (HTK), offers the advantages of better tissue perfusion due to lower viscosity, less reperfusion hyperkalemia, and significantly lower cost. However, studies have suggested a higher incidence of graft pancreatitis and an increased rate of graft loss with HTK, particularly with longer cold ischemic times.^{8,9} Approaches using either a two-layer storage method with UW or an HTK solution and a second layer of highly oxygenated perfluorocarbon or the attachment of the pancreas to a low-pressure pulsatile perfusion system are being investigated.

The current gold standard immunosuppression for pancreas transplants is antibody induction therapy, tacrolimus, mycophenolate mofetil (MMF), and corticosteroids; this has led to a 40% decrease in incidence of rejection and an increase in 1-year graft survival to more than 90%.⁹ UNOS registry data show that HLA matching has no effect on the outcome in SPK, whereas for PAK and PTA, a beneficial effect is seen by matching at the A and B loci.¹⁰ The reported 1-, 3-, and 5-year patient and graft survival rates by use of these techniques and criteria are given in Figure 106.2.¹

Surgical Procedure

Current practice is to transplant the whole pancreas with a cuff of duodenum, which preserves the blood supply of the head of the pancreas and provides a means to drain exocrine secretions into either the small bowel (enteric drainage) or the bladder (Figs. 106.3 and 106.4).¹ From 2004 to 2008, the majority of the pancreas transplants in the United States were enterically drained (SPK 85%, PAK 82%, PTA 78%; Fig. 106.5).¹ The graft may be placed in the right iliac fossa like a kidney, intraperitoneally, and vascularized from the common iliac vessels so that the secreted insulin enters the systemic circulation. However, an alternative is to construct the venous anastomosis to the superior mesenteric vein, allowing more physiologic insulin output through the portal circulation. Currently, 15% to 20% of enterically drained transplants use portal drainage. In either approach, an interposition graft from the donor (typically a Y graft containing common iliac with external and internal branches) is used to provide inflow from the recipient common iliac artery to the graft superior mesenteric and splenic arteries. Some surgeons have advocated reconnection of the graft gastroduodenal artery if the pancreaticoduodenal arcades are not intact.

Bladder drainage allows monitoring for rejection by measurement of urinary amylase and also avoids enterotomy-associated risks of infection and leak. The disadvantages of bladder drainage include susceptibility to dehydration, metabolic acidosis, and frequent bladder-related complications. Primary enteric drainage avoids these complications and is more physiologic but does not allow urinary amylase monitoring. With improved surgical techniques, increased use of real-time ultrasound, and percutaneous needle biopsy, the outcomes of portal enteric drainage now match those of bladder drainage. Bladder drainage is still appropriate in the following settings: with a history of major abdominal surgery; in the presence of Crohn's disease or other small bowel disease; and for older patients with less cardiovascular reserve, in whom a laparotomy may be avoided through a smaller lower quadrant retroperitoneal incision similar to that for a kidney transplant. Pancreas transplants with venous outflow to the superior mesenteric vein can be placed either anterior to the small bowel mesentery or in a retroperitoneal position behind the ascending colon, where the superior mesenteric vein is reached from the side. Surgical outcomes have not differed whether the venous drainage is systemic or portal. Although portal drainage is considered more physiologic and avoids hyperinsulinemia, these benefits are not well characterized.

Immunosuppression

Most centers use antibody induction therapy during the first 1 to 2 weeks after transplantation. OKT3 has largely been replaced by antithymocyte globulin (ATG).¹¹ Other centers use an

Figure 106.3 Pancreas transplant with enteric (portal) drainage.

Figure 106.4 Pancreas transplant with bladder drainage. The pancreas may be placed in either the intraperitoneal or extraperitoneal position.

interleukin-2 receptor antagonist (basiliximab, daclizumab) or, most recently, an anti-CD25 antibody (alemtuzumab).^{12,13} Antibody-mediated rejection may be more common than acute cellular rejection in patients receiving alemtuzumab.¹⁴ Most centers employ triple-drug maintenance immunosuppression with tacrolimus (or less commonly cyclosporine), MMF (or rarely azathioprine), and corticosteroids. There is increasing evidence of equivalent success with rapid corticosteroid elimination or corticosteroid avoidance protocols. Some centers replace the calcineurin inhibitor or MMF with sirolimus. With the more

There has been a shift toward enterically drained compared with bladder-drained pancreas transplantation. PAK, pancreas transplantation after living related or unrelated kidney transplantation; PTA, pancreas transplantation alone; SPK, simultaneous pancreas-kidney transplantation. (Redrawn from reference 7.)

profound immunosuppressive induction produced by the newer antibodies (particularly alemtuzumab), there have been reports of immunosuppression protocols limited to a depleting antibody and a single additional agent.^{13,15,16} Fortunately, cytomegalovirus (CMV) infection rates appear to be lower in corticosteroid-free regimens,¹⁷ although there has been some increase in CMV infection in those receiving depleting antibody therapies.¹²

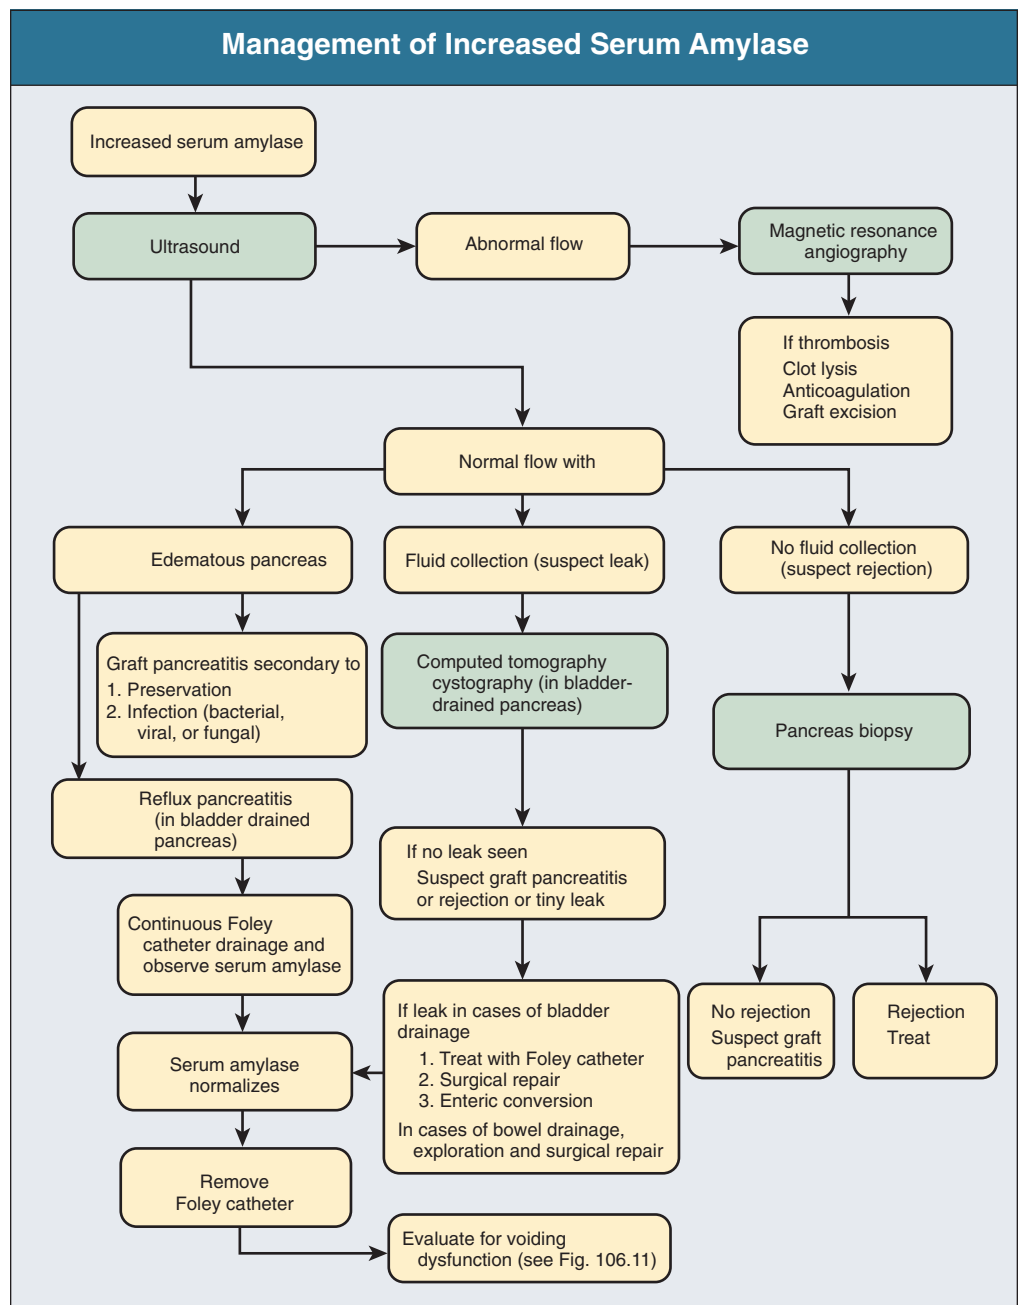

Graft Monitoring

The causes of pancreas graft dysfunction and the evaluation process are shown in Figures 106.6 to 106.8.

During the immediate perioperative phase, intravenous insulin is used to decrease the stress on the transplanted pancreas by maintaining serum glucose concentration around 100 to 120 mg/dl (5.5 to 6.6 mmol/l). Serum glucose values are not an early marker of pancreas dysfunction; elevations are observed only after significant parenchymal pancreatic damage has occurred. With bladder drainage, urinary amylase excretion is measured on 12-hour collections and reported as units per hour. During the first 1 to 2 weeks after transplantation, serum amylase may be elevated and urinary amylase decreased as a result of pancreatic preservation injury. Stable serum and urinary levels are usually attained within 2 weeks after transplantation. Thereafter, an elevated serum amylase or lipase concentration and a decreased urinary amylase concentration (typically by more than 20% of baseline) indicate possible graft injury, which must be evaluated. Both enterically drained and bladder-drained transplants may manifest elevated serum amylase and serum lipase concentrations, which are moderately sensitive markers of pancreas rejection. However, other conventional causes of pancreatitis can still occur. Elevated fasting glucose and 2-hour postprandial glucose levels are relatively late indicators and only indicate dysfunction without revealing cause.

Ultrasound examination of the pancreas transplant is performed frequently in the early post-transplantation period to rule

Figure 106.6 Management of increased serum amylase after pancreas transplantation.

out vascular thrombosis. If the pancreas cannot be well visualized by ultrasound scan, magnetic resonance imaging and angiography may be informative. Any inflammatory state can also yield images of an edematous gland; however, other than for vascular thrombosis, imaging generally cannot reveal the cause of the dysfunction.

Biopsy of the pancreas transplant remains the gold standard for diagnosis of acute or chronic rejection. A biopsy may be performed at certain time points by protocol or at times of graft dysfunction to identify rejection or other causes of pancreatic injury before irreversible tissue damage has occurred. The easiest approach is a percutaneous biopsy with ultrasound or computed tomography guidance. Cystoscopic biopsy through the duodenal cuff is used in bladder-drained transplants if the percutaneous technique is not possible because of difficult visualization or

overlying bowel.¹⁸ The most frequent complication of percutaneous biopsy is a perigraft hematoma or transient hematuria, but rarely seen are pancreatitis, arteriovenous fistula, abdominal hemorrhage, bowel perforation requiring exploration, and even graft loss.

Treatment of pancreas rejection is similar to that of kidney rejection and generally involves pulse intravenous corticosteroids or antilymphocyte antibodies (see Chapter 100).

Treatment response is achieved by following the return of serum amylase and lipase or urinary amylase to baseline values. Imaging can be used to show resolution of edema and inflammation. Repeated biopsy, usually at a 2-week interval, is required to show resolution of more moderate or severe rejections and to look for histologic signs of the development of chronic rejection.

Causes of Pancreas Graft Dysfunction	
Rejection	
Ductal obstruction	
Vascular: arterial/venous thrombosis (partial/complete), arteriovenous fistula	
Volume depletion	
High calcineurin inhibitor levels	
Graft pancreatitis (preservation, viral, bacterial, or fungal)	
In cases of bladder drainage	
Reflux pancreatitis	
Urinary tract infection	
Anastomotic leak	
Bladder outflow obstruction	
In cases of enteric drainage	
Anastomotic leak	
Bowel obstruction	

Figure 106.7 Causes of pancreas graft dysfunction.

Evaluation of Pancreas Graft Dysfunction	
Assessment	Tests
Laboratory tests	Serum amylase, blood glucose human anodal trypsinogen, cyclosporine or tacrolimus levels, C-peptide In bladder-drained cases, urinary amylase and urine culture
Doppler ultrasound	Pancreatic blood flow, peripancreatic fluid collection, pancreatic ductal dilation In bladder-drained cases, evidence of bladder outlet obstruction
Computed tomography ± cystography	Looking for leak and collections; this is performed by cystography in bladder-drained cases

Figure 106.8 Evaluation of pancreas graft dysfunction.

Patients with isolated pancreas rejection have an increased risk for kidney graft loss, supporting the concordance of acute rejection in the majority of patients.¹⁹ In SPK or PAK patients, when biopsy of the pancreas cannot be performed safely, a kidney transplant biopsy may be used as a surrogate indicator in conjunction with serum and urine tests.

Antimicrobial Prophylaxis

Antimicrobial prophylaxis is much like that for a kidney transplant alone. Trimethoprim-sulfamethoxazole is prescribed for the prevention of urinary tract infections and *Pneumocystis* infection. Oral clotrimazole or nystatin is used for the prevention of oral candidiasis; some centers use fluconazole for prophylaxis of *Candida* urinary tract infections and intra-abdominal fungal or yeast infections. Oral acyclovir is given to patients with a history of herpes simplex infection and to patients who are CMV negative and receive CMV-negative donor organs. Otherwise, valacyclovir or ganciclovir is given for 3 months after transplantation

to all patients who are CMV positive or who receive CMV-positive organs. Patients treated for rejection are typically returned to any discontinued anti-infectious prophylaxis for 1 to 3 months after rejection therapy.

Metabolic Monitoring

In addition to monitoring of the serum and urinary concentrations of amylase and the serum concentration of lipase, serum creatinine, potassium, magnesium, and bicarbonate levels must be monitored. Magnesium wasting is common with calcineurin inhibitors and frequently requires oral supplementation. With bladder drainage, there is high urinary loss of bicarbonate in pancreatic exocrine secretions, which may require as much as 130 mmol/day of replacement. Without replacement, patients develop metabolic acidosis with nausea and vomiting, which may lead to volume depletion, hypotension (exacerbated by underlying autonomic neuropathy), and graft thrombosis. Oral sodium bicarbonate, typically 2 g four times daily, is needed. Fluid intake should be 2.5 to 3 l/day to accommodate pancreatic and renal fluid outputs. This intake may be difficult to achieve because abdominal bloating from diabetic gastroparesis is exacerbated by the large fluid intake and the gas released from sodium bicarbonate tablets. Patients who are unable to maintain adequate oral intake may require intravenous fluids including sodium bicarbonate. In patients who require intravenous repletion for longer than 1 month, consideration should be given to placement of a tunneled venous catheter or a buried central venous port for fluid administration.

Surgical Complications

Surgical complications of pancreas transplantation are shown in Figure 106.9. Superficial infections and deep-seated abscesses are commonly fungal. The source of fungal contamination is thought to be the duodenal segment. Therefore, topical antibiotic and antifungal solutions are used to irrigate the donor duodenum during procurement and implantation. Patients commonly receive 24 to 48 hours of postoperative antibiotics and fluconazole.

The causes of wound drainage are seroma, lymphocele, pancreatic fistula from either the tail or the anastomosis to the bladder or bowel, wound dehiscence, and preservation pancreatitis. Preservation pancreatitis may lead to wound drainage of whitish yellow, thick, noninfectious material formed from the enzymatic digestion of tissue, leading to fat necrosis and saponification. Wound drainage is seen more often with the extraperitoneal placement of the pancreas and also occurs when a pancreas from an obese donor is used. It is also associated with a mild increase in serum amylase concentration, low urinary amylase excretion, and variable changes in the serum glucose concentration.

Vascular complications occur in about 5% of patients and include arteriovenous fistulas due to surgery or biopsy, venous and arterial thrombosis, and rarely mycotic aneurysms. The pancreas is a low blood flow organ; vascular thrombosis rates were previously as high as 10%, but current rates are below 5%. Means of reducing the rate of thrombosis include minimization of warm and cold ischemia, procurement procedures involving a no-touch technique using the duodenum and spleen as handles, and postoperative antiplatelet activity with aspirin. In cases with longer cold ischemia times, a more edematous graft, or concern about low inflow or outflow, intravenous heparin is sometimes used for the first few postoperative days. Partial thrombosis

Surgical Complications Following Pancreas Transplantation			
Type of Complication	Presentation	Diagnostic Findings and Testing	Treatment Options
Abscess	Fever, erythema of wound, wound drainage	Elevated white cell count (WBC), fluid collection on computed tomography (CT) scan, pus on aspiration	Open or percutaneous drainage
Graft pancreatitis	Pain over allograft, lower abdominal pain	Elevated serum amylase, enlarged pancreas allograft	Octreotide or somatostatin Foley catheter if bladder drained
Lymphocele	Mass on palpation, urgency if bladder compression	Fluid collection on CT scan, clear fluid on aspiration	Open or percutaneous drainage
Wound drainage	Pancreatic goo, no erythema	Culture, CT scan to rule out deep abscess	Local wound care
Dehiscence	Wound open		Wound care/surgical closure
Arterio venous fistula	Hematuria, abdominal bleeding	Doppler ultrasound, angiography	Embolization, surgical repair
Graft thrombosis	Elevated blood sugars Bloody urine if bladder drained	Low serum and urine amylase, sepsis-like syndrome, ultrasound or magnetic resonance imaging	If partial, thrombolytic therapy or anticoagulation (high risk of bleeding), graft pancreatectomy
Pancreatic fistula/leak (bowel drained)	Pain over allograft, sepsis, peritonitis, fever	Elevated WBC, fluid collection on CT scan	Surgical drainage and repair

Figure 106.9 Surgical complications following pancreas transplantation.

may resolve with thrombolytic therapy or anticoagulation. More extensive thrombosis requires urgent surgical intervention. Complete graft thrombosis, especially in the immediate postoperative period, mandates urgent graft removal to prevent sepsis syndrome or a more diffuse hypercoagulable state, leading to further vascular thrombotic complications such as myocardial infarction.

Nonsurgical Complications

Nausea and vomiting are common, and causes include gastroparesis, constipation, cholelithiasis or esophageal reflux developing from motility problems, and esophagitis with or without CMV disease. Antiemetics plus histamine H_2 blockers or proton pump inhibitors are usually effective therapy and are given for 2 to 3 months after transplantation. Persistent symptoms may require prokinetic agents (metoclopramide or erythromycin). Diarrhea can be caused by immunosuppressive medications, intrinsic gut motility problems, food intolerance, or CMV or other infection. Constipation is treated with increased fluid intake, dietary modification, increased activity, and regular low-dose schedule of stool softeners or laxatives.

Orthostatic hypotension may worsen after transplantation as a consequence of prolonged bed rest in the presence of diabetic autonomic neuropathy. Treatment may include a salt-loading diet, with a mineralocorticoid (fludrocortisone) or an α -adrenergic agonist (midodrine).²⁰

Urologic Complications

Urologic complications are common after bladder drainage (Fig. 106.10).²¹ Pretransplantation bladder dysfunction due to diabetic autonomic neuropathy causes a large-capacity bladder, decreased bladder sensation, increased residual urine volume, and decreased urinary flow rates. Bladder function is worsened by the autoaugmentation of the bladder by the added duodenal segment.

Preoperative urodynamics are abnormal in up to 43% of patients but do not predict post-transplantation urologic complications such as reflux pancreatitis or infections.²²

Urinalysis is difficult to interpret with the bladder-drained pancreas. The urine contains white cells from duodenal mucosal sloughing and may be leukocyte esterase positive without bacteriuria. Urine protein excretion is elevated to 1 to 3 g/day in most patients, composed of pancreatic enzymes, immunoglobulins, other globulins, albumin, and digested fragments of these proteins. Urinary albumin, if it is measurable in the presence of enzymatic degradation, may come from the transplanted or native kidneys.

Macroscopic hematuria occurs in up to 28% of bladder-drained pancreas recipients. Early hematuria is related to surgical trauma to the bladder or duodenal mucosa near the cystoduodenostomy site and usually clears with diuresis or bladder irrigation.²⁰ Continuous bladder irrigation requires caution because the cystoduodenostomy is vulnerable to rupture if the drainage catheter becomes obstructed. Late hematuria, beyond 2 to 4 weeks after transplantation, can arise from anastomotic bleeding, duodenal mucosal sloughing or ulceration, reflux pancreatitis, cystitis, graft thrombosis, rarely arteriovenous fistulas, and pseudoaneurysms. Evaluation should include ultrasound, urine culture, and cystoscopy. If the pancreas appears to be the source on cystoscopy, biopsy of the pancreas may be required to determine the exact cause.

Microscopic hematuria should be evaluated. Evidence is sought for recurrent disease, new renal disease, or genitourinary malignant neoplasms.

Urinary Tract Infections

Risk factors for urinary tract infection after pancreas transplantation include large bladder capacity, incomplete bladder emptying, high bladder urine pH (due to pancreatic bicarbonate), bladder and urethral mucosal irritation from activated pancreatic

Urologic Complications of Bladder-Drained Pancreas Transplants				
Complication	Etiology	Presentation	Evaluation	Treatment Options
Urinary tract infection (UTI)	Diabetic bladder dysfunction (DBD)	Asymptomatic, or dysuria, fever, sepsis	Urine culture; check postvoid residual, if elevated urodynamics	Culture-specified antibiotics, prophylactic antibiotics Female: double and timed voiding, clean intermittent catheterization (CIC) Male: α -adrenoceptor blockers to aid bladder emptying, CIC, bladder neck/prostate incision. If treatment failure enteric conversion: Foley catheter drainage
Reflux pancreatitis	DBD	Asymptomatic or pain over pancreas allograft, elevated serum amylase	Check serum amylase, computed tomography (CT) cystogram to exclude leak or duct obstruction	If DBD: double and timed voiding, CIC, α -blockers to aid bladder emptying. If multiple and symptomatic episodes: bladder neck/ prostate incision or enteric diversion
Duodenal cystotomy leak	Ischemic injury to duodenal cuff, cytomegalovirus or other infection, rejection, DBD	Pain over allograft, or peritonitis, elevated serum amylase	Check serum amylase, elevated creatinine, leak on CT cystogram	Foley catheter drainage, if small If early, open surgical repair with resection and closure of layers, evaluate for DBD post recovery. If late, consider enteric conversion
Urethritis/dysuria syndrome, occasional urethral disruption	UTI or DBD causing activation of pancreatic enzymes with digestion of urethral mucosa	Dysuria, urinary retention, hematuria	Check postvoid residual, low-grade UTI; once recovered, evaluate for DBD	Foley catheter, analgesics, empirical treatment of UTI If multiple and symptomatic: enteric conversion

Figure 106.10 Urologic complications of bladder-drained pancreas transplants.

enzymes with the loss of mucosal barrier, prolonged bladder catheterization, and immunosuppression.²³ Most centers administer oral antibacterial and antifungal prophylaxis for up to 6 to 12 months or indefinitely after transplantation.

Urinary reflux pancreatitis, which causes pancreas graft dysfunction, may be associated with perigraft abdominal pain and fever. It is often a result of poor bladder function and requires drainage with a bladder catheter for 5 to 7 days and assessment of bladder dysfunction (Fig. 106.11).

A urethritis dysuria syndrome occurs in 2% to 8% of pancreas recipients with bladder drainage and is caused by uroepithelial exposure to the activated pancreatic proenzymes trypsinogen, chymotrypsinogen, and procarboxypeptidase. Pancreatic exocrine secretions consist of bicarbonate, amylase, lipase, and proenzymes, which are activated by the enterokinase in the graft duodenal brush border. Increased intravesical enzyme activation occurs with low-grade urinary infections and urinary stasis, and patients will develop voiding pain or penile, glandular, meatal, or vulval ulceration. Enzyme activation may be minimized by treatment of low-count bacteriuria, increase in fluid intake, and frequent voiding. If emptying does not improve with α -blockers, continuous Foley catheter drainage for 7 to 10 days has been effective.

Enteric Conversion

This is an option for most of the chronic urologic complications associated with bladder-drained pancreas transplantation. The indications are urethral disruption, recurrent urine leak, persistent bleeding, chronic urinary tract infection, dysuria, recurrent

hypovolemia, and metabolic acidosis. The conversion rate varies from 8% to 14%. It is ideal to wait until 6 to 12 months after transplantation, when possible, to allow monitoring of urine amylase for early rejection episodes.

Late Complications

Late complications after pancreas transplantation typically fit into one of two patterns. There can be an acute presentation of graft rejection, not different from that seen in early graft dysfunction. The second pattern is more insidious; chronic inflammatory states from chronic rejection, ischemia, or infection may lead to gradual graft loss. Unfortunately, there is no practical test to measure small decrements in graft function in the way serum creatinine allows detection of kidney transplant dysfunction. Although it is lacking the necessary sensitivity, patients are typically asked to measure 2-hour postprandial glucose levels (which are more sensitive than fasting blood glucose levels) weekly and to report trends or sudden increases to the physician.

IMPACT OF PANCREAS TRANSPLANTATION ON DIABETIC COMPLICATIONS

Pancreas transplantation is performed to eliminate the need for exogenous insulin and the risk of severe hypoglycemic episodes and to stop or to reverse the consequences of hyperglycemia. Well-functioning pancreas transplants result in normal fasting blood glucose concentrations, normal glycated hemoglobin levels, and only slightly abnormal oral glucose tolerance testing.²⁴

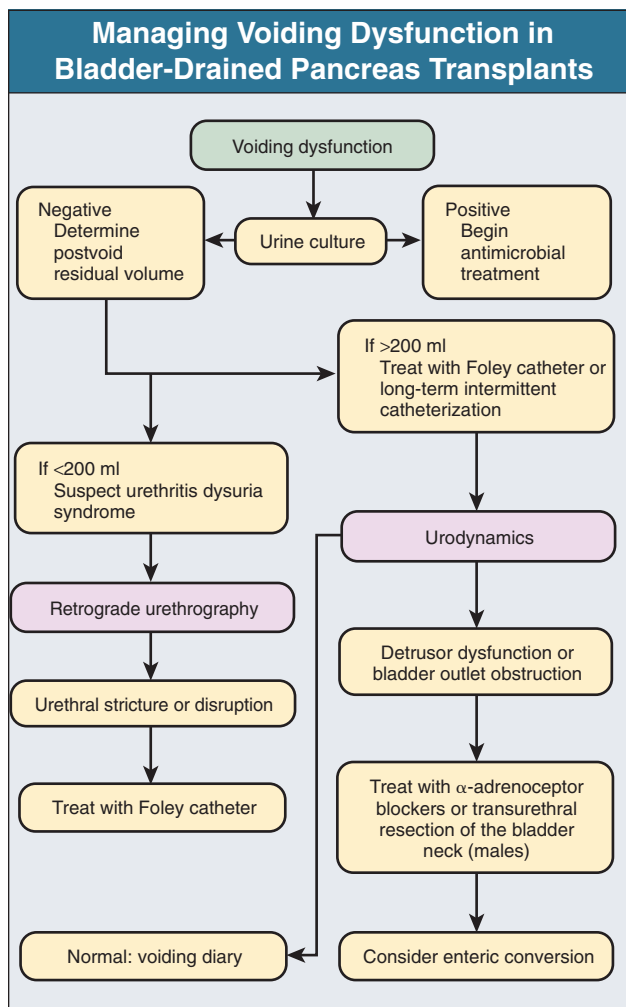

Figure 106.11 Management of post-transplantation voiding abnormalities. (From reference 21.)

Hypoglycemia

Although severe hypoglycemia is rare, mild hypoglycemia may develop in patients with a well-functioning pancreas graft once low baseline immunosuppression has been reached, especially in those patients who have regained little weight after transplantation and who are physically active. Postprandial hypoglycemic episodes are not always symptomatic. They are associated with high-carbohydrate meals, excessive intake of caffeine or alcohol, excessive exercise, and, in some patients with hypoglycemia, circulating anti-insulin antibodies. This is not often a significant clinical problem and is usually resolved by avoidance of carbohydrate-rich meals.

A major benefit of pancreas transplantation is restoration of glucagon secretory responses to hypoglycemia. In type 1 diabetes, the absence of functional β cells within the islet eliminates the normal physiologic response by which intra-islet insulin tonically dampens secretion of glucagon from α cells. Consequently, diabetic subjects are usually at risk of prolonged hypoglycemia secondary to injected insulin because there is failure of the normal counterregulatory action of glucagon on the liver to increase glycogenolysis. Despite the fact that the transplanted pancreas is placed ectopically and does not develop vagal control, the transplanted organ has normal glucagon responses to insulin-induced hypoglycemia and resultant counterregulation of

hypoglycemia through increased hepatic glucose production. After pancreas transplantation, hypoglycemic awareness returns, as well as partial return of defective epinephrine secretion during insulin-induced hypoglycemia.

Hyperglycemia

Post-transplantation hyperglycemia may be caused by pancreas graft dysfunction, inadequate insulin release secondary to high tacrolimus or occasionally cyclosporine levels, resistance to insulin secondary to corticosteroids, weight gain, and inadequate physical activity. Although the use of tacrolimus has reduced pancreas graft rejection, it also decreases insulin gene transcription. If laboratory and imaging evaluations (see Fig. 106.8) are normal, hyperglycemia is the result of decreased insulin production or else of peripheral insulin resistance, which can be identified by measurement of glucose utilization rates and glucose/arginine-potentiated insulin secretion. In the absence of graft rejection, post-transplantation hyperglycemia should first be managed by dietary intervention and exercise. Insulin may be needed initially but can often be discontinued as oral hypoglycemic agents begin to take effect. Sulfonylureas are effective therapy. Hyperglycemia secondary to rejection is a late event and indicates irreversible graft damage. Because of the increased risk of rejection with manipulation of immunosuppression, minimizing the tacrolimus dose or changing to cyclosporine or sirolimus should not usually be considered until these measures have failed.

Microvascular Complications

Retinopathy

In a prospective funduscopy study of SPK patients during 45 months, there was a decreased need for post-transplantation laser therapy, and the diabetic retinopathy showed stabilization in 62%, improvement in 21%, and progression in 17%.²⁵ In the postoperative period, patients may develop neovascularization and retinal hemorrhages if preoperative blood glucose control is very poor and blood glucose normalizes rapidly after transplantation. Patients remain at risk of retinal detachment because of scarring secondary to previous retinal damage. Cataracts are more common after transplantation.

Neuropathy

Sensory and motor nerve conduction velocities improve rapidly after pancreas transplantation and then stabilize.²⁶ Greater recovery is seen in nonobese, younger, shorter patients; in those with better initial action potential amplitudes; in those not receiving renal replacement therapy; and possibly in those receiving angiotensin-converting enzyme inhibitors or angiotensin receptor blockers.²⁷ The recovery of action potential amplitudes is gradual, continuing to improve up to 5 years beyond transplantation. Recovery is more complete in sensory than in motor nerves.

There is greater improvement in autonomic reactivity and gastric emptying in SPK recipients compared with diabetic kidney-only transplant recipients.²⁸ If autonomic symptoms are severe at the time of pancreas transplantation, improvement is unlikely.

Nephropathy

Early diabetic nephropathy is characterized by increased glomerular basement membrane thickness and an increase in mesangial volume. Renal transplant biopsy specimens from diabetics with SPK and kidney-only transplants within 2.5 years of

transplantation show glomerular basement membrane thickness within the normal range. After 2.5 years from transplantation, 92% of renal biopsy specimens from the kidney-pancreas recipients have a normal glomerular basement membrane thickness compared with only 35% of the biopsy samples from the kidney-only recipients; relative mesangial volume was normal in 82% of the biopsy specimens from kidney-pancreas recipients compared with only 12% in the kidney-only recipients.²³ Thus, concurrent pancreas transplantation decreases the occurrence of the changes of diabetic nephropathy that may result in allograft loss.²⁹

Vascular Disease

Successful kidney-pancreas transplantation results in a significant improvement in the control of hypertension compared with kidney transplant alone in type 1 diabetics.³⁰ Increase in peripheral vascular disease has been reported in kidney-pancreas transplant recipients compared with kidney-alone transplant recipients³¹; however, another study found the same prevalence of peripheral vascular disease after pancreas transplantation as occurred in diabetic kidney-only recipients who refused pancreas transplantation for nonmedical reasons and in nondiabetic kidney transplant recipients.³² Encouragingly, one study showed that after a 10-year mean observation period, the progression of macrovascular diseases (cerebrovascular, coronary, and peripheral vascular) was significantly lower in recipients with a functioning SPK compared with a kidney transplant alone.⁴

A study using intravital microscopic evaluation of nail bed and conjunctival vasculature found improved vascularization (as assessed by a reduction in venular diameter, increased number of arterioles per unit area, and elevation of the perfusion capacity) only in kidney-pancreas recipients.³³

Quality of Life and Social Issues

Pancreas transplantation is a very stressful event and can tax even the strongest of family relationships. Pretransplantation debilities (decreased vision, neuropathy, muscle weakness, orthostatic symptoms) can be exacerbated by the surgery and immunosuppressive medications. Patients who smoke or drink alcohol and are without family support do not survive as long after transplantation. However, kidney-pancreas transplant recipients with social support and well-functioning grafts report an increased global quality of life and frequently return to work, although the number returning to work is not much different from those receiving a kidney transplant alone.³⁴ In living donor simultaneous kidney-pancreas transplantation, preliminary results suggest a maintained level of quality of life for donors while recipients experience improvement.³⁵

Pregnancy After Pancreas Transplantation

Within 1 year of transplantation, menstruation and ovulation return in most women of childbearing age. The United States National Transplantation Pregnancy Registry has reported 62 pregnancies in 40 SPK patients.³⁶ The outcomes were 50 live births, three therapeutic and 10 spontaneous abortions (one twin reduction), and one ectopic twin pregnancy. The newborn outcomes were prematurity (39 of 50), low birth weight (32 of 50), other neonatal complications (28 of 50), and neonatal death (1 of 50). Ten patients had rejections that resulted in grafts loss, and 58% of the patients required cesarean section. Hypertension, prematurity, preeclampsia, and growth retardation

frequently complicated the pregnancies, even with good renal function. Gestational diabetes appeared in 3%.

All transplant recipient pregnancies require high-risk obstetric care. Consensus opinion is that pregnancy is safe by 1 year after transplantation under the following conditions: no rejection has occurred in the past year, graft function is stable, no active infections that could have a negative impact on the fetus (e.g., CMV infection) are present, and the patient is not taking any teratogenic medications.³⁷ MMF has been linked to structural malformations, and patients planning on conception should transition to another agent 6 weeks before trying to conceive.³⁸ Cyclosporine and tacrolimus levels often decline during pregnancy and require close monitoring to prevent rejection. Cesarean section is not mandatory; vaginal deliveries, however, must be observed for signs of allograft duodenal rupture. The average gestational period is 35 ± 2 weeks; the average birth weight is 2150 ± 680 g. There is no evidence that the children of transplant recipients are more likely to have abnormal development.

The management of other medical issues does not differ from that in kidney-only transplant recipients (see Chapters 101 and 102).

ISLET TRANSPLANTATION

Islet transplantation, with its reduced antigen load, technical simplicity, and low morbidity, has the potential to dramatically improve the quality of life of individuals with type 1 diabetes. The first series of islet allotransplantations in type 1 diabetic patients were reported in 1977.³⁹ There were then sporadic reports in the 1990s of insulin independence for extended periods after islet allotransplantation.^{40,41} Autotransplantation studies then demonstrated that a critical mass of 300,000 IE (islet equivalents) could reestablish and maintain insulin independence beyond 2 years.⁴² To date, the longest period of insulin independence after autotransplantation is more than 16 years.⁴³

Islet After Kidney Transplantation

The initial allogeneic islet transplants in patients with type 1 diabetes were performed in the 1980s and 1990s in patients with end-stage renal disease as sequential islet after kidney (IAK) or simultaneous islet-kidney transplantation. Because the kidney transplant patients were already immunosuppressed, the IAK transplant procedure carried a minimal risk. However, there could be destabilization of the transplanted kidney and also islet dysfunction because most kidney transplant immunosuppression protocols included corticosteroids. Nevertheless, there were beneficial effects from improved glycemic control on both survival and function of transplanted kidneys.⁴⁴ Metabolic control (hemoglobin A_{1c} level and fasting glycemia) improved after IAK even in patients receiving low-dose corticosteroids. Adverse events included procedure-related pleural effusion and cholecystitis.⁴⁵

Of the 237 well-documented allotransplants recorded in the Islet Transplant Registry from 1990 to 2000, less than 12% of recipients were insulin free at 1 year after transplantation. The reasons for this failure rate may include subtherapeutic islet implant mass, high rate of engraftment failure, islet damage in the liver (the site of implantation) by direct local toxic effects of the immunosuppressants, ineffective immunosuppression that fails to prevent rejection, recurrent autoimmune diabetes, and islet functional exhaustion. Four criteria were associated with insulin independence: (1) an islet implant mass of more than

6000 IE/kg, (2) a cold ischemia (preservation) time of less than 8 hours, (3) an induction therapy with polyclonal antibodies such as antilymphocyte globulin or thymoglobulin (ATG), and (4) the liver as the favored implantation site. Early immunosuppressive regimens were relatively ineffective in preventing allograft rejection compared with their effect on vascularized pancreas grafts. Most if not all immunosuppressive agents were associated with impaired β -cell function and reduced graft revascularization.

More success with insulin independence was reported in non-uremic type 1 diabetics transplanted with an average of 800,000 islets by use of the Edmonton protocol, a corticosteroid-free immunosuppression regimen of daclizumab, sirolimus, and low-dose tacrolimus. Although follow-up of this cohort has since confirmed long-term C-peptide production with therapy that is safe and well tolerated, insulin independence is maintained in only a minority.⁴⁵ There has since been an exponential increase in clinical islet transplant activity; more patients with type 1 diabetes have now received islet transplants in the past 5 years than in the entire preceding 30-year history of islet transplantation.

Technique of Islet Transplantation

The current technique of islet transplantation involves deceased donor pancreas procurement, organ preservation, enzymatic isolation of the islets, purification, and percutaneous injection of sterile islets into the liver through the portal vein by a catheter placed under radiographic guidance (Fig. 106.12). Although accessing of the portal vein percutaneously is relatively invasive, the entire procedure can be performed on an outpatient basis. Effective mechanical and physical methods to seal the catheter track reduce the risk of postprocedural bleeding.⁴⁶ Bleeding related to the procedure (23%), thrombus in segmental branches of the portal vein (8%), and punctured gallbladder (3%) are the most observed acute complications after islet transplantation.⁴⁷

There is still a need for greater availability of transplantable islets as well as for improvement in islet engraftment and preservation. Although previous reports indicate that the two-layer method for pancreas preservation improves islet isolation outcome, our recent data show no beneficial effect of the two-

Figure 106.12 Current clinical islet cell transplantation protocol. The retrieved donor pancreas (1) is preserved (2) with a two-layer storage method using University of Wisconsin solution (UW) over a layer of highly oxygenated perfluorocarbon (PFC). The pancreas is distended with collagenase and placed in a digestion chamber (3). The disrupted exocrine and endocrine elements are purified by centrifugation (4), and the islet preparation free from exocrine elements is transplanted by intrahepatic portal vein infusion (5). (Modified from reference 48.)

layer method on islet isolation and transplantation outcomes.⁴⁶ Islet culture for 24 to 48 hours in antioxidant-enriched medium has improved the quality of islet preparations and facilitated the shipment of islets between centers.⁴⁷

Medical Complications

There are also complications of islet transplantation that are not directly related to the procedure itself.⁴⁴ Changes consistent with fatty liver are reported in 22% of subjects who had magnetic resonance imaging after transplantation. Mouth ulcers occur in 90% of subjects, usually responding to simple antiseptic measures or topical triamcinolone ointment together with a reduction in the dose of sirolimus. Diarrhea (60%) and acne (52%) are frequent. Forty-three percent of recipients complained of edema, severe enough in 12% to necessitate a change in the immunosuppressive regimen. Weight loss is common.

Glycemic Control and Insulin Independence

Successful islet transplantation establishes normal hemoglobin A_{1c} levels, although the fasting glucose concentration tends to be slightly elevated, and there is often impaired glucose tolerance. Another difference between successful pancreas and islet transplants is that placement of islets within the liver results in failure of the α -cell response to hypoglycemia, even though there is responsiveness to intravenous arginine. In a recent analysis, 82% of 118 islet recipients in three North American centers were insulin free at 1 year.⁴⁷ However, in a 5-year follow-up in Edmonton,⁴¹ only 7.5% maintained insulin independence, although 82% had detectable C-peptide (Fig. 106.13). The median duration of insulin independence was 15 months.

Immunosuppressive Regimens

Tacrolimus, cyclosporine, and corticosteroids are diabetogenic through increased peripheral insulin resistance or by direct islet cell toxicity. Oral administration increases portal venous drug concentrations and the possibility of significant injury to intra-hepatic islet grafts. Most programs use corticosteroid-free and calcineurin inhibitor-sparing protocols for islet or kidney recipients with different combinations of MMF and sirolimus. MMF reduces early pancreas rejection rates. Insulin independence has now been achieved with islet grafts derived from non-heart-beating donors and after sequential kidney-islet transplantations using sirolimus-based therapy. Islet engraftment can also be improved with use of a calcineurin inhibitor-free regimen with profound T-cell depletion.⁴⁴ Anti-T cell therapy using ATG or OKT3 may be associated with a cytokine storm, which is toxic to islets, and newer induction agents (anti-interleukin-2 receptor blockers) may be particularly useful to minimize cytokine release.

A number of new immunosuppressive agents that offer the potential for more islet-friendly approaches are now entering clinical trials. These include combinations of biologic agents, such as ATG, rituximab, and alemtuzumab; novel anti-T cell biologic agents, some of which offer the prospect of inducing tolerance based on animal studies; and agents that produce costimulatory blockade.

Kidney Disease in Liver, Cardiac, Lung, and Hematopoietic Cell Transplantation

Colm C. Magee

There is growing recognition that kidney disease can complicate all forms of solid organ nonrenal transplantation.¹ Kidney disease can occur in the immediate pretransplantation period, in the early postoperative period, or during the long term. In general, it is associated with longer hospitalization, higher morbidity, higher mortality, and more expense. Although there are organ-specific factors (such as the high prevalence of hepatitis C virus infection in liver transplant recipients) that have an impact on the incidence and severity of kidney disease, some useful generalizations can be made.

GENERIC ISSUES OF KIDNEY DISEASE IN NONRENAL SOLID ORGAN TRANSPLANTATION

Use of Serum Creatinine and Derived Equations to Measure Glomerular Filtration Rate

Transplant candidates and recipients often have low muscle mass and low creatinine generation. Hence, a mildly elevated serum creatinine concentration may “hide” severe kidney disease. This is particularly relevant in the pretransplantation patient with liver failure.² Such patients should have glomerular filtration rate (GFR) estimated by creatinine clearance (which will tend to overestimate) or preferably by iothalamate clearance (where it is available). Of the various serum creatinine-based equations to estimate GFR, the Modification of Diet in Renal Disease (MDRD) equation appears to correlate best with “true” post-transplantation GFR; however, even this equation has limited accuracy in all forms of solid organ transplantation.²

Nephrotoxicity of Calcineurin Inhibitors

The introduction of the calcineurin inhibitor (CNI) cyclosporine in the 1980s revolutionized the field of organ transplantation and dramatically improved the survival of nonrenal allografts. More than 30 years later, the CNIs cyclosporine and tacrolimus remain a cornerstone of immunosuppression in recipients of nonrenal allografts.¹ However, there is little doubt that CNIs contribute significantly to both acute kidney injury (AKI) and chronic kidney disease (CKD) in these recipients. There is speculation that CNI nephrotoxicity is more severe in nonrenal than in renal transplantation because (1) dosing and blood concentrations of CNIs tend to be higher in nonrenal transplantation and (2) the lack of normal innervation of the transplanted kidney may protect it from early CNI injury. CNIs also exacerbate post-transplantation hypertension and diabetes mellitus, which cause renal damage in the long term.

Acute CNI nephrotoxicity is thought to be mainly a prerenal syndrome due to vasoconstriction of the afferent glomerular arteriole (see also Chapter 97). Tubular damage and microvascular disease may occur in more severe cases. In the early post-transplantation period, AKI is usually multifactorial, and it is difficult to quantify the degree to which CNI toxicity is contributing to the problem. In practice, doses of CNIs are often temporarily reduced in the setting of AKI. CNI-induced thrombotic microangiopathy (TMA) is rare in nonrenal transplant recipients. Chronic CNI nephrotoxicity is probably due to prolonged renal ischemia and other effects, such as direct stimulation of renal fibrogenesis. Typically, the patient is hypertensive, and there is a steady fall in GFR, most marked in the first 6 to 12 months after transplantation (Fig. 107.1).³ Dipstick urinalysis shows minimal or no hematuria and minimal or mild proteinuria. Urine protein-creatinine ratio or 24-hour urine collections confirm low-grade proteinuria. Renal histology shows interstitial fibrosis, arteriolar hyalinosis, arteriosclerosis, and secondary focal glomerulosclerosis. There may also be features of chronic TMA. In practice, renal biopsies are rarely performed unless there are clinical features suggestive of a renal disorder other than CNI toxicity.

Not surprisingly, the presumed high prevalence of chronic CNI nephrotoxicity has generated interest in low-dose or zero-dose CNI protocols. Just as in renal transplantation, these typically involve use of mycophenolate mofetil (MMF) or sirolimus.^{1,4} However, there is still understandable reluctance to pursue such protocols because CNIs are considered such effective immunosuppressive agents, and an alternative organ replacement therapy analogous to dialysis is not available for other organ transplant recipients if severe rejection occurs. MMF has the advantage of being non-nephrotoxic; sirolimus has the disadvantages of potentiating the nephrotoxicity of cyclosporine and sometimes inducing proteinuria. Similar nephrotoxic interactions have been reported between everolimus and cyclosporine.⁵ CNI-sparing strategies are discussed in more detail later.

Another strategy is to use tacrolimus as the *de novo* CNI or to switch from cyclosporine to tacrolimus if there is evidence of nephrotoxicity (cyclosporine is still commonly prescribed as the *de novo* CNI in heart and lung transplantation). The rationale is that tacrolimus provides equivalent or even better immunosuppression at doses and concentrations that are less nephrotoxic than cyclosporine. Furthermore, tacrolimus is associated with less hypertension and hyperlipidemia (which might exacerbate CKD) than cyclosporine. Conversely, it is associated with more post-transplantation diabetes mellitus. One study of healthy volunteers showed that tacrolimus (at trough concentrations of 5 to

15 ng/ml) had less effect on blood pressure and GFR than cyclosporine (at trough concentrations of 100 to 200 ng/ml),⁶ but such studies in nonrenal transplant recipients have yielded conflicting results.

The utility of calcium channel blockers in ameliorating CNI nephrotoxicity in renal transplantation remains controversial, and there is limited evidence of such benefit in nonrenal transplantation. Experimental studies suggest that agents that block the renin-angiotensin system (RAS) may provide protection against the arteriolar hyalinosis and tubulointerstitial injury associated with chronic CNI use. The benefits on renal function of dosing cyclosporine based on C₂ (serum levels 2 hours after dosing) rather than C₀ (trough) concentrations remain unproven.

Figure 107.1 Changes in iothalamate measured GFR in individual patients after lung transplantation. Note the variation in GFR before transplantation and the large fall in many patients within the first 6 months. (Modified from reference 3.)

Acute Kidney Injury in the Immediate Pretransplantation Period

Not surprisingly, AKI can occur in the days to weeks immediately before liver, heart, or (less commonly) lung transplantation. Typically, the etiology of AKI is either prerenal (e.g., renal hypoperfusion or hepatorenal syndrome) or intrarenal (ischemic or toxic acute tubular necrosis) or a combination of both. AKI may develop on a background of CKD. A mildly elevated serum creatinine concentration may mask a significant fall in GFR in malnourished patients with severe organ failure.

Rates of reported AKI vary widely; rates may be modified by varying definitions of AKI, organ-specific risks of AKI, and center variability in the type of patients listed for transplantation. Management of AKI focuses on treatment of the underlying cause and provision of dialytic support according to standard criteria. Because the patients are critically ill, continuous renal replacement therapy (CRRT) may be preferred to intermittent hemodialysis, but there are no randomized controlled trials showing improved outcomes with this modality in this setting.

When severe or prolonged AKI occurs before planned transplantation, estimation of the degree of reversibility becomes very important, as presumed irreversible severe kidney injury is generally a contraindication to transplantation or shifts the management toward simultaneous dual organ (e.g., liver and kidney) transplantation. This is an area of ongoing debate in liver and, to a lesser extent, cardiac transplantation and is discussed in detail later. The general advantages and disadvantages of simultaneous dual organ transplantation are shown in Figure 107.2.

Although kidney biopsy might be useful in determining the degree of reversibility, in practice it is not commonly performed. This reflects the technical difficulties in performing the procedure in critically ill patients, particularly because of the high risk of coagulopathy, and the catastrophic consequences if a biopsy were complicated by a major bleed.

Acute Kidney Injury in the Early Post-transplantation Period

AKI is also common in the days to weeks after transplantation. This reflects several factors: pretransplantation renal function may have been compromised, the transplanted organ may have poor initial function, high doses of CNIs and other nephrotoxic agents may be prescribed, and the invasive surgery and high-dose immunosuppression predispose to severe infection (Fig. 107.3). AKI is associated with higher mortality in the early postoperative period.^{7,8} This is likely to reflect both the association of AKI with other severe complications and also its direct effects on mortality. In those who survive, AKI is associated with increased risk

Figure 107.2 Advantages and disadvantages of simultaneous kidney and other solid organ transplantation. AKI, acute kidney injury; ESRD, end-stage renal disease.

Advantages and Disadvantages of Simultaneous Kidney and Other Solid Organ Transplantation	
Advantages	Disadvantages
Potentially provides much better renal function over the short and long term	Surgery more technically complex and prolonged
	Not needed when the AKI is reversible
Single donor - potential for lower cumulative dose of immunosuppression (as opposed to kidney transplantation later)	Deprives patients with 'definite' ESRD of a kidney transplant

Causes of AKI After Solid Organ Transplantation		
Prerenal	Intrarenal (ATN)	Postrenal
Hypovolemic shock (e.g. aggressive diuresis)	Prolonged shock	Rare
Cardiogenic shock (e.g. severe cardiac allograft dysfunction)	Cyclosporine/tacrolimus	
Distributive shock (e.g. sepsis)	Aminoglycosides, Amphotericin	
Cyclosporine/tacrolimus	IV Contrast Hydroxyethylstarch, IV Ig	

Figure 107.3 Causes of AKI after solid organ transplantation. ATN, acute tubular necrosis; IV Ig, intravenous immune globulin.

Figure 107.4 Cumulative incidence of CKD (eGFR <30 ml/min per 1.73 m²) after transplantation of various solid organs. (Modified from reference 9.)

for development of CKD.⁹ Prevention or minimization of post-transplantation AKI involves careful selection of patients for transplantation, meticulous perioperative care, and avoidance of nephrotoxic agents.

Management of established AKI focuses on treatment of the underlying cause and provision of dialytic support according to standard criteria. Intermittent hemodialysis and CRRT are both used. Delayed introduction or reduced dosing of CNIs is sometimes employed, usually under the cover of induction antibody immunosuppression. How much this strategy improves renal function remains unclear.

Chronic Kidney Disease

With the higher number of solid organ transplants being performed worldwide and the longer survival of recipients, the absolute number of recipients with CKD has increased. In the largest and most comprehensive study to date, the cumulative incidence of post-transplantation CKD (defined as eGFR <30 ml/min per 1.73 m²) at 5 years varied from 7% to 21% (Fig. 107.4).⁹ By multivariate analysis, the following pretransplantation variables

increased the risk for development of CKD: increasing age, female gender, white or black (as opposed to Asian) ethnicity, lower GFR, diabetes mellitus, hypertension, hepatitis C virus infection, and need for dialysis. The following post-transplantation variables were also implicated: postoperative AKI and initial use of cyclosporine (as opposed to tacrolimus).⁹ These risk factors have been confirmed in other studies.

Many studies have also confirmed that whatever the transplanted organ, development of CKD, and especially of end-stage renal disease (ESRD), portends a poor prognosis (Fig. 107.5). Recipients with CKD have a relative risk of death of 4.6 compared with those without CKD.⁹ The risk is highest in those with ESRD, but even in those not on dialysis, the relative risk of death was doubled.⁹ Although it has not been well studied, CKD in this setting is presumably associated with the same complications as in nontransplant recipients, including anemia, hypertension, fluid overload, and bone and mineral disorders. Indeed, these complications might be more severe in nonrenal transplant recipients because of other risk factors. For example, antiproliferative immunosuppressants exacerbate anemia and corticosteroids exacerbate metabolic bone disease.

Figure 107.5 Mortality associated with stage 4 and stage 5 CKD in organ transplant recipients. (Data from Scientific Registry of Transplant Recipients.)

Management of Chronic Kidney Disease

The MDRD equation (despite its limitations) is useful in identifying CKD in these patients. In all patients with rising serum creatinine or falling GFR, referral to a nephrologist should be considered. The initial evaluation should include thorough review of renal function in the peritransplantation period and exposure to nephrotoxins. If urinalysis shows moderate or severe proteinuria or hematuria or both, renal biopsy should be considered; it can be highly informative in identifying renal diseases other than CNI nephrotoxicity.¹⁰⁻¹²

Close consultation with the primary transplant team is important. When CNI toxicity is deemed the main cause of CKD (as it is in the majority of cases), reduction in CNI dosage for patients at *low immunologic risk* should be considered. To maintain adequate immunosuppression, if the patient is receiving azathioprine, a change to MMF should be considered; if the patient is already receiving MMF, the dose should probably be increased. An alternative strategy is to substitute sirolimus for the CNI; this should not be done in the early post-transplantation period because of the adverse effects of sirolimus on wound healing. Finally, some have advocated switching of cyclosporine to low-dose tacrolimus, although the supporting data are less compelling. The majority of studies of CNI reduction or cessation in these settings are small and have limited follow-up.

The general management of CKD has not been well studied in nonrenal transplant recipients, but it seems reasonable to employ the same strategies used in the nontransplant CKD population. Thus, hypertension, anemia, and hyperparathyroidism should be managed according to standard guidelines. Although there is experimental evidence that angiotensin-converting enzyme (ACE) inhibitors might have important antifibrotic effects in nonrenal transplant CKD, there are no trials showing improved renal outcomes with ACE inhibitors or angiotensin receptor blockers compared with other antihypertensive agents. In practice, lifestyle modification and several antihypertensive drugs are usually required to achieve target blood pressure.

In those with severe CKD, planning for renal replacement therapy should begin early. The majority are treated with hemodialysis rather than with peritoneal dialysis. With either modality, mortality is much higher compared with matched non-transplant controls.^{13,14} For example, outcomes have been reported in 21 cardiac transplant recipients treated with peritoneal dialysis; peritonitis was more common than in controls, but no patient was reported to have died of a direct complication of peritoneal dialysis.¹³ Pending further studies, it seems that the choice of dialysis modality should be dictated by patient-specific factors.

There seems little doubt that in those fit for the procedure, sequential kidney transplantation is the best form of renal replacement therapy. Because patients are already transplanted, the addition of the renal allograft does not imply a huge increase in immunosuppression (typically, this is increased only in the perioperative period). When it is feasible, a preemptive live donor transplant is probably the best option. Initial mortality is higher in nonrenal transplant recipients receiving a kidney transplant as opposed to staying on the waiting list (reflecting the complications of surgery and more immunosuppression), but mortality during the medium and long term is much lower.⁹

Prevention of Chronic Kidney Disease

The rate of development and progression of CKD can probably be reduced by minimizing post-transplantation AKI (see earlier) and by rigorous control of hypertension during the long-term. Clearly, safe and effective non-CNI or low-dose CNI protocols would be an important advance in preventing severe CKD. Studies using induction antibody with corticosteroids, MMF, and low-dose tacrolimus are encouraging in this regard.^{15,16}

BK Virus Nephropathy

This is a much-feared complication of kidney transplantation. Fortunately, although BK viruria is occasionally noted after liver,

heart, or lung transplantation, the absolute risk of BK viremia and BK virus nephropathy remains low. This probably reflects the lack of a “second hit” to the native kidneys, such as HLA mismatching or inflammation. Nevertheless, BK virus nephropathy should be considered in the differential diagnosis of “unexplained” renal dysfunction after solid organ transplantation, especially because more intensive maintenance immunosuppressive protocols involving combined MMF and tacrolimus are being increasingly used.

Acute Kidney Injury in the Late Post-transplantation Period

Severe AKI occasionally occurs late after transplantation. The major causes are shown in Figure 107.3. Severe rhabdomyolysis has been reported, usually when statins are prescribed with cyclosporine and an inhibitor of the cytochrome P-450 system, such as diltiazem or the azoles. Treatment of late AKI is of the underlying cause plus the usual supportive measures.

KIDNEY DISEASE IN LIVER TRANSPLANTATION

AKI is common before liver transplantation. Indeed, use of the MELD (Model for End-stage Liver Disease) scoring system (which measures severity of hepatic dysfunction and risk of death) to guide allocation of deceased donor liver allografts in the United States means that a raised serum creatinine concentration increases the chances of the patient being offered a liver transplant.¹⁷ The most common causes of AKI before transplantation are hepatorenal syndrome (see Chapter 72) and acute tubular necrosis or both. Prolonged hepatorenal syndrome may cause acute tubular necrosis. Glomerulonephritis is relatively common (cirrhosis is associated with IgA nephropathy and hepatitis C with membranoproliferative glomerulonephritis) but is rarely the cause of severe pretransplantation kidney disease. If renal replacement therapy is required, CRRT is often preferred, in part because it is thought to have less effect than intermittent dialysis on intracranial pressure.

Post-transplantation AKI is also common and is usually multifactorial.⁸ In one recent series, 37% of liver transplants were complicated by some degree of AKI, 19% requiring renal replacement therapy.⁸ Requirement for renal replacement therapy was associated with higher 30-day and 1-year mortality. Pretransplantation AKI associated with hepatorenal syndrome often but not always improves if the transplant is successful.

Although relatively low doses of CNIs are traditionally used in liver transplantation (because rejection is less of a concern than in other solid organ transplants), CKD remains common and is associated with higher mortality (see Fig. 107.5).⁹ Thus, although CNIs are the most important cause of CKD, other factors must play a role. These include the high prevalence of hepatitis C and hepatitis B viral infections (which predispose to glomerulonephritis) and the high prevalence of diabetes (which predisposes to a number of renal problems, including diabetic nephropathy and renal infection).

Protocols involving reduction or cessation of CNIs have shown promising results. Delayed introduction of tacrolimus, with the cover of interleukin-2 receptor blockade, was recently shown in liver transplantation to better preserve renal function while maintaining excellent allograft and patient outcomes.¹⁶ *De novo* use of sirolimus is not recommended as there is some concern that it may be associated with hepatic artery thrombosis.

Recommended Indications for Simultaneous Liver-Kidney Transplant in Patients Listed for Liver Transplant

CKD with GFR ≤ 30 ml/min

AKI or HRS with creatinine ≥ 2 mg/dl (176 μ mol/l) and dialysis ≥ 8 weeks

CKD with biopsy showing $>30\%$ glomerulosclerosis or 30% interstitial fibrosis

Figure 107.6 Recommended indications for simultaneous liver-kidney transplantation in patients listed for liver transplantation. AKI, acute kidney injury; CKD, chronic kidney disease; GFR, glomerular filtration rate; HRS, hepatorenal syndrome. (Modified from reference 17.)

The number and percentage of simultaneous liver-kidney transplants have increased greatly in the United States during the last 10 years. In 1998, for example, there were 98; in 2008, there were 376 (approximately 6% of total liver transplants).¹⁸ The principal reason is that the MELD system heavily weights higher serum creatinine concentration and prioritizes patients with renal dysfunction. Although patients with severe pretransplantation kidney disease do benefit from a combined transplant procedure, there is concern that too many simultaneous liver-kidney transplants are being performed and that current practice is depriving “real” ESRD patients of deceased donor kidney transplants.¹⁹ The main issue, of course, is deciding which patients are likely to have meaningful renal recovery after liver transplant alone. Complicating factors in this setting are the known poor accuracy of serum creatinine (and equations based on it) in estimating GFR and concerns about the high risk of renal biopsy. Single-center studies suggest that use of a combination of clinical and histologic criteria allows effective prediction of which patients will benefit most from simultaneous liver-kidney transplantation.^{20,21} These centers used iothalamate clearance to measure GFR in patients with suspected AKI. Renal biopsy was performed by the percutaneous or transjugular method and had a moderate rate of complications^{20,21}; some believe that it adds little discriminating value.²² A recent consensus conference has provided recommendations as to who should receive simultaneous liver-kidney transplants (Fig. 107.6).¹⁷

KIDNEY DISEASE IN CARDIAC TRANSPLANTATION

Preoperative AKI is common. In the largest reported study, 1% of heart transplant recipients required renal replacement therapy before transplantation.⁹ The main cause of AKI is renal hypoperfusion due to severe congestive heart failure (type II cardio-renal syndrome; see Chapter 71). Ventricular assist devices are sometimes used as a bridge to cardiac transplantation and can improve renal function in this setting. Interestingly, there is emerging evidence that venous congestion is independently associated with the presence of AKI, although whether therapies based on reducing central venous pressure improve renal outcomes remains to be proven. In some cases, there may also be a component of chronic kidney injury due to renovascular disease or hypertension or atheroembolism.

Postoperative AKI is also common. In addition to the causes shown in Figure 107.3, factors that may be important after cardiac transplant surgery are prolonged aortic cross-clamping,

large fluid volume shifts, and prolonged allograft ventricular dysfunction.

CKD is now well recognized as an important and common complication during the medium and long term (see Fig. 107.4). The cumulative incidence of stage 4 or stage 5 CKD in cardiac transplant recipients has been reported as 11% at 5 years, lower than in bowel, liver, or lung transplant recipients.⁹ However, others have reported actuarial rates of ESRD as high as 20% after 10 years.²³ The principal cause of CKD after cardiac transplantation is CNI toxicity. Several studies have shown that early or late renal dysfunction is a risk factor for death after cardiac transplantation; furthermore, cardiac transplant recipients on dialysis have poorer survival compared with other ESRD patients.^{14,24}

A number of studies have assessed reduction or cessation of CNIs in patients with significant CKD after cardiac transplantation. The majority are small and single center and have shown improvement in GFR with no adverse effects on the allograft.²⁵⁻²⁸ However, these studies are of patients at low immunologic risk and do not have long-term follow-up. Indeed, one recent report warned of high rates of rejection after patients were switched to a corticosteroid plus MMF protocol.²⁹ Another pilot study showed concerning outcomes with a *de novo* CNI-free protocol,³⁰ which cannot at present be recommended.

As in liver transplantation, the question of whether the patient is best served by heart-alone or simultaneous heart and kidney transplantation sometimes arises. The concern here, again, is the reversibility of renal failure. The absolute number of such dual transplants remains low but is steadily increasing in the United States (62 in 2008, equivalent to about 1% of total heart transplants). Single-center reports have shown mixed results. One recent registry analysis found that simultaneous heart and kidney (as opposed to heart-alone) transplantation benefited only low-risk cases among those with eGFR below 33 ml/min.³¹ Consensus guidelines have not yet been developed. At this time, it seems reasonable to limit the combined transplants to cases with severity of kidney disease similar to that shown in Figure 107.6.

KIDNEY DISEASE IN LUNG TRANSPLANTATION

Preoperative AKI is less common and severe, as evidenced by the fact that only 0.1% of lung transplant recipients are reported to require dialysis before transplantation.⁹ CKD may be present before transplantation, however, because of diabetes mellitus or high exposure to aminoglycosides (mainly in patients with cystic fibrosis).

AKI after lung transplantation is common; in one series, 56% of patients had at least a doubling of serum creatinine in the first 2 weeks after transplantation.⁷ AKI can occur for the usual reasons shown in Figure 107.3, but a number of factors specific to lung transplantation may be important. First, aggressive diuresis is often prescribed to minimize any pulmonary edema in the allograft.⁷ Second, nephrotoxic antimicrobial agents, such as aminoglycosides and amphotericin, are sometimes required to treat resistant or severe infections.^{7,12} Acute oxalate nephropathy leading to irreversible renal failure was recently described in two lung transplant recipients.¹¹ The pathogenesis is thought to involve gut hyperabsorption of oxalate because of impaired fatty acid absorption and altered gut flora. Although it is probably rare, this “new disease” emphasizes the importance of maintaining a broad differential diagnosis for any kidney disease occurring after solid organ transplantation and the utility of performing a renal biopsy when the clinical presentation is unusual.

As with other forms of post-transplantation CKD, the most common cause is CNI toxicity.¹² CNI dosing tends to be higher because of the increased risk of rejection in lung transplantation. A small number of studies have reported improvements in GFR when doses of CNIs were reduced, but more data are needed before this can be routinely recommended. If CNI reduction is attempted, it seems prudent to use MMF rather than sirolimus as additional immunosuppression in view of the risk of pneumonitis with sirolimus. *De novo* use of sirolimus is not recommended as it may cause breakdown of the bronchial anastomosis.

Interestingly, patients with pulmonary hypertension appear to have a lower GFR immediately before transplantation than do those with other diagnoses but exhibit a less severe fall in GFR after transplantation.³ This probably reflects the adverse effects of pulmonary hypertension on renal perfusion and reversal of these effects after successful lung transplantation. Simultaneous lung-kidney transplantation is rarely performed.¹⁸

KIDNEY DISEASE IN HEMATOPOIETIC CELL TRANSPLANTATION

The general purpose of hematopoietic cell transplantation (HCT) is to allow administration of otherwise lethal (and ideally curative) doses of chemoradiotherapy, followed by engraftment of stem or progenitor cells for marrow recovery. Most commonly, HCT is used to treat hematologic malignant neoplasms, but other indications now include certain nonhematologic malignant neoplasms, severe genetic disorders (such as immunodeficiencies), and severe autoimmune diseases.³² Stem and progenitor cells may be harvested from bone marrow, peripheral blood, or umbilical cord blood. Conventional *myeloablative* HCT uses intensive conditioning regimens involving high-dose chemotherapy and radiotherapy to ablate cancer cells and bone marrow; the hematopoietic system is then reconstituted by infusion and engraftment of stem cells. In allogeneic myeloablative HCT, non-self stem cells are used; in autologous myeloablative HCT, the patient's own cells are used. The toxicities of myeloablative regimens generally exclude older and sicker patients. *Nonmyeloablative* conditioning regimens have been developed to allow allogeneic HCT in such patients. These so-called “mini-allo” or “reduced conditioning” transplants involve less toxic conditioning; eradication of disease is mediated in part by allogeneic immunologic mechanisms, the “graft-versus-tumor” effect. In both forms of allogeneic HCT, acute and chronic graft-versus-host disease (GVHD) can be problematic; CNIs are typically prescribed to prevent and to treat this complication. The three main target organs of GVHD are the liver, gastrointestinal tract, and skin.

Tens of thousands of HCTs are performed worldwide every year.³² It is now recognized that AKI and CKD are common complications of HCT and are associated with higher early and late mortality.³³ The types of HCT and their associated renal complications are shown in Figure 107.7.

Acute Kidney Injury After Hematopoietic Cell Transplantation

AKI is common after HCT, but its incidence and severity depend on the type of HCT (and on the definition of AKI used in reported series). It is common after myeloablative allogeneic HCT, reflecting the propensity of this regimen to cause profound immunosuppression (with associated risk of severe sepsis)

The Three Types of Haemopoietic Cell Transplantation and Their Associated Renal Complications			
	Myeloablative allogeneic	Myeloablative autologous	Nonmyeloablative allogeneic
Diseases treated	Many leukemias, NHL, myelodysplastic syndromes	Lymphomas, multiple myeloma	As for myeloablative allogeneic
Used in patients > 60 years	Rarely	Sometimes	Commonly
Cormorbidities permissible before HCT	Minimal	Minimal	Some
Intensity of conditioning regimen	High	High	Low
GVHD after HCT	Common	None	Common
CNIs used routinely	Yes	No	Yes
Incidence of AKI	Very common; sometimes severe	Common	Common; rarely severe
Causes of AKI	VOD, shock syndromes, nephrotoxic drugs, CNIs	Shock syndromes, nephrotoxic drugs; occasionally VOD	CNIs
Incidence of CKD	Common	Common (but less severe than myeloablative allogeneic)	Mild forms probably common
Causes of CKD	Irrversible AKI, Renal TMA, CNIs, ?GVHD	Irreversible AKI	Pretransplant mild CKD, irreversible AKI, CNIs, ?GVHD

Figure 107.7 The three types of hematopoietic cell transplantation and their associated renal complications. AKI, acute kidney injury; CKD, chronic kidney disease; CNIs, calcineurin inhibitors; GVHD, graft-versus-host disease; NHL, non-Hodgkin's lymphoma; TMA, thrombotic microangiopathy; VOD, veno-occlusive disease.

Causes of Kidney Disease According to Time After HCT		
Immediate	Early (AKI in first 3 months)	Late
Tumor lysis syndrome	<i>Prerenal</i>	Thrombotic Microangiopathy*
Marrow/stem cell infusion toxicity	Hypovolemia	CNI toxicity
	Hepatorenal syndrome CNI toxicity	Irreversible AKI Membranous nephropathy/other glomerular diseases
	<i>Intrarenal</i> Ischemic toxic ATN (shock syndromes, aminoglycosides, amphotericin)	Recurrence of original disease which then affects kidneys (e.g. myeloma)*
	<i>Postrenal</i> Hemorrhagic cystitis	?GVHD

Figure 107.8 Causes of kidney disease according to time after HCT. *Can cause AKI also. AKI, acute kidney injury; ATN, acute tubular necrosis; CNI, calcineurin inhibitor; GVHD, graft-versus-host disease; HCT, hematopoietic cell transplantation. (Modified from reference 36.)

and liver damage (with associated risk of hepatorenal syndrome; see later); furthermore, CNIs are routinely prescribed for the first 100 days after transplantation. Severe AKI is least common after nonmyeloablative HCT (even though patients are older and sometimes sicker), reflecting the shorter period of pancytopenia and rarity of veno-occlusive disease of the liver as a post-transplantation complication; in fact, the principal cause of AKI is probably CNI toxicity.³⁴ Severe AKI necessitating dialysis is relatively rare.³⁴ Myeloablative autologous HCT has an intermediate incidence of AKI. Whatever the form of HCT, if dialysis

is required for severe AKI, the overall prognosis is usually very poor (early mortality >70%).³⁵

It is helpful to consider the causes of AKI according to the time period after HCT (Fig. 107.8).³⁶ Tumor lysis syndrome is now rare because the tumor burden at the time of HCT is rarely high and appropriate prophylaxis is widely used.³⁷ Marrow/stem cell infusion toxicity has been described after autologous HCT and is probably mediated by toxic cell breakdown products and DMSO, a cryopreservative used in the storage of autologous stem cells. DMSO can induce hemolysis of red blood cells and

ultimately pigment nephropathy. Advances in cryopreservation and administration have made this complication rare.

Within the first few weeks of myeloablative HCT, when the conditioning regimen has caused pancytopenia, mucositis of the gastrointestinal tract, and liver damage, recipients are at high risk of many forms of AKI.³⁷ These include prerenal syndromes due to hepatorenal syndrome (see later) and hypovolemia (induced by vomiting and diarrhea or bleeding). Neutropenia predisposes to septic shock. Exposure to nephrotoxic agents, such as amphotericin, aminoglycosides, intravenous contrast agents, and CNIs, is relatively common and may also precipitate acute tubular necrosis. Obstructive uropathy is much rarer but can be due to severe hemorrhagic cystitis or fungal infection of the collecting system. Causes of hemorrhagic cystitis include high-dose cyclophosphamide and viral infection (by adenovirus or BK virus). BK virus nephropathy and adenovirus nephropathy have been described but appear to be rare.

Veno-occlusive Disease of the Liver

This is also known as hepatic sinusoidal obstructive syndrome and is one of the most common causes of severe AKI after myeloablative HCT, particularly allogeneic myeloablative HCT (see Figs. 107.7 and 107.8). The pathophysiologic mechanism is thought to involve radiotherapy- and chemotherapy-induced damage to the endothelium of hepatic venules with subsequent venular thrombosis and sinusoidal and portal hypertension.³⁷ Risk factors for development of veno-occlusive disease (VOD) include allogeneic HCT, older age, female gender, preexisting liver disease, use of cyclophosphamide or busulfan in the conditioning regimen, and exposure to methotrexate, progesterone, or antimicrobial drugs.³⁵

Clinically, VOD is manifested as a form of hepatorenal syndrome. Frequently, there is a precipitating factor such as sepsis.³⁷ VOD generally appears during the first 30 days after HCT. The initial symptoms and signs are weight gain, edema, and ascites, then right upper quadrant abdominal pain and tenderness, jaundice, and abnormal liver function test results. Falling urine output, low urine sodium, and rising serum creatinine then follow.³⁷ The severity of disease varies. In mild to moderate cases, sodium and fluid restriction, diuresis, and analgesia may be required, and the syndrome eventually resolves. Severe VOD complicated by liver and renal failure (and frequently respiratory failure) carries a mortality approaching 100%.

The differential diagnosis includes acute GVHD of the liver, sepsis, drug-induced cholestasis, gallstone disease, and hepatotoxic effects of parenteral nutrition. The diagnosis of VOD is usually based on the typical clinical and laboratory features. On occasion, liver biopsy is needed to confirm the diagnosis.

Current preventive strategies for VOD include avoidance of precipitating factors when possible and use of ursodeoxycholate or low-dose heparin. Thrombolytics have been tested for treatment of severe VOD; not surprisingly, severe bleeding limits their use. The most encouraging therapy to date is defibrotide, a single-stranded oligonucleotide with antithrombotic and fibrinolytic effects on microvascular endothelium, but with apparently few systemic adverse effects.³⁸ Defibrotide is also showing encouraging results as a preventive agent.

Management of Acute Kidney Injury After Hematopoietic Cell Transplantation

Evaluation of the patient should be as for any patient with hospital-acquired AKI but with particular focus on the possible

contribution of hepatorenal syndrome to the clinical picture. The patient's cancer diagnosis, conditioning regimen, and type of HCT should be carefully reviewed. When it is possible, further exposure to nephrotoxic drugs should be minimized (e.g., effective alternatives to amphotericin are now often available). If CNI trough concentrations are high, then reduction in dose should be considered. No randomized controlled trials have compared intermittent hemodialysis with CRRT in this setting. Whatever the modality used, the prognosis in those who develop severe AKI after HCT is poor. Continuous therapies do offer some potential advantages. In the setting of hepatorenal syndrome, there is some evidence that they are associated with less increase in intracranial pressure. In addition, the daily obligate fluid intake in these patients is frequently massive, and fluid balance is most easily controlled by a continuous dialysis technique. Vascular access can be problematic because of thrombocytopenia and neutropenia predisposing to bleeding and infection, respectively.

Chronic Kidney Disease After Hematopoietic Cell Transplantation

CKD is an important long-term complication of HCT, particularly allogeneic HCT.³³ Reported rates vary widely; in one recent review, the incidence in those surviving at least 100 days after HCT was 17%.³⁹ As recipients of HCT are living longer, CKD may become more prevalent, similar to the situation in solid organ transplants described earlier.

GVHD is thought not to affect the kidneys directly. However, there is evidence that GVHD or its accompanying inflammatory state may cause glomerular disease (see later); some believe that it may play a role in the pathogenesis of CKD also.⁴⁰

The causes of CKD are shown in Figure 107.8.

Thrombotic Microangiopathy

Subacute or chronic renal TMA is probably the most common cause of CKD (particularly severe CKD) after HCT,³³ although this is disputed by some.⁴⁰ It typically is first manifested 4 to 12 months after HCT. Characteristic clinical features are slowly rising serum creatinine concentration, hypertension, and disproportionate anemia (see also Chapter 28). Dipstick urinalysis shows variable proteinuria and hematuria. Some cases have a much more fulminant presentation, however (e.g., as a severe nephritic syndrome). Careful review of previous laboratory test results will often show evidence of a low-grade TMA: intermittent or persistent elevation in plasma lactate dehydrogenase, low serum haptoglobin, low platelets, low hemoglobin, and sometimes schistocytosis. Renal imaging is usually unremarkable. Kidney biopsy is rarely required unless the presentation is atypical as the biopsy findings are unlikely to significantly alter management, and the biopsy carries increased risks in patients with thrombocytopenia and other morbidities. Histopathology typically shows microthrombi in arterioles and glomerular capillaries, mesangiolysis, glomerular basement membrane duplication, and tubular injury with interstitial fibrosis (Fig. 107.9).³⁷

The main cause of TMA after HCT is thought to be direct damage to the renal endothelium, and possibly the tubulointerstitium, by the chemoradiotherapy conditioning regimen (particularly the radiotherapy component).^{33,37} Renal tissue has much slower turnover than mucosal cells do and thus manifests chemoradiotherapy damage much later. Other factors, such as infection, GVHD, CNIs, and activation of the RAS, may play a facilitating role (Fig. 107.10).³⁶

Figure 107.9 Thrombotic microangiopathy after allogeneic HCT. Renal biopsy specimen from a patient who had undergone allogeneic HCT and developed subacute renal failure 12 months later. Periodic acid–Schiff staining shows near-occlusion of two small arteries by subintimal connective tissue and swollen endothelium (black arrows). The glomerulus shows thickened capillary walls with “double contours” and segmental occlusion and collapse of capillaries (orange arrows). (Courtesy Dr. H. Rennke, Harvard Medical School, Boston, USA.)

Treatment of renal TMA after HCT is mainly supportive. Prevention involves renal shielding (from irradiation damage) and avoidance of other nephrotoxic agents at the time of conditioning. One small trial showed a trend toward better renal outcomes with captopril as opposed to placebo in patients who had undergone total body irradiation and HCT.⁴¹

Calcineurin Inhibitor and Sirolimus Nephrotoxicity

CNIs are routinely prescribed after allogeneic HCT to prevent and to treat GVHD. Long-term use of CNIs very likely contributes to CKD, as described before in solid organ transplantation.⁴² However, as CNIs are often stopped after 3 to 6 months (unless there is ongoing GVHD), their contribution to CKD is generally thought to be limited. The contribution of CNIs to chronic renal TMA is unclear. There is a high incidence of TMA when sirolimus is added to CNI therapy, but fortunately this is often reversible.⁴³

Glomerular Disease

Nephrotic syndrome has been described after both allogeneic and autologous HCT. In allogeneic HCT, it appears to be strongly associated with the presence of GVHD and to respond

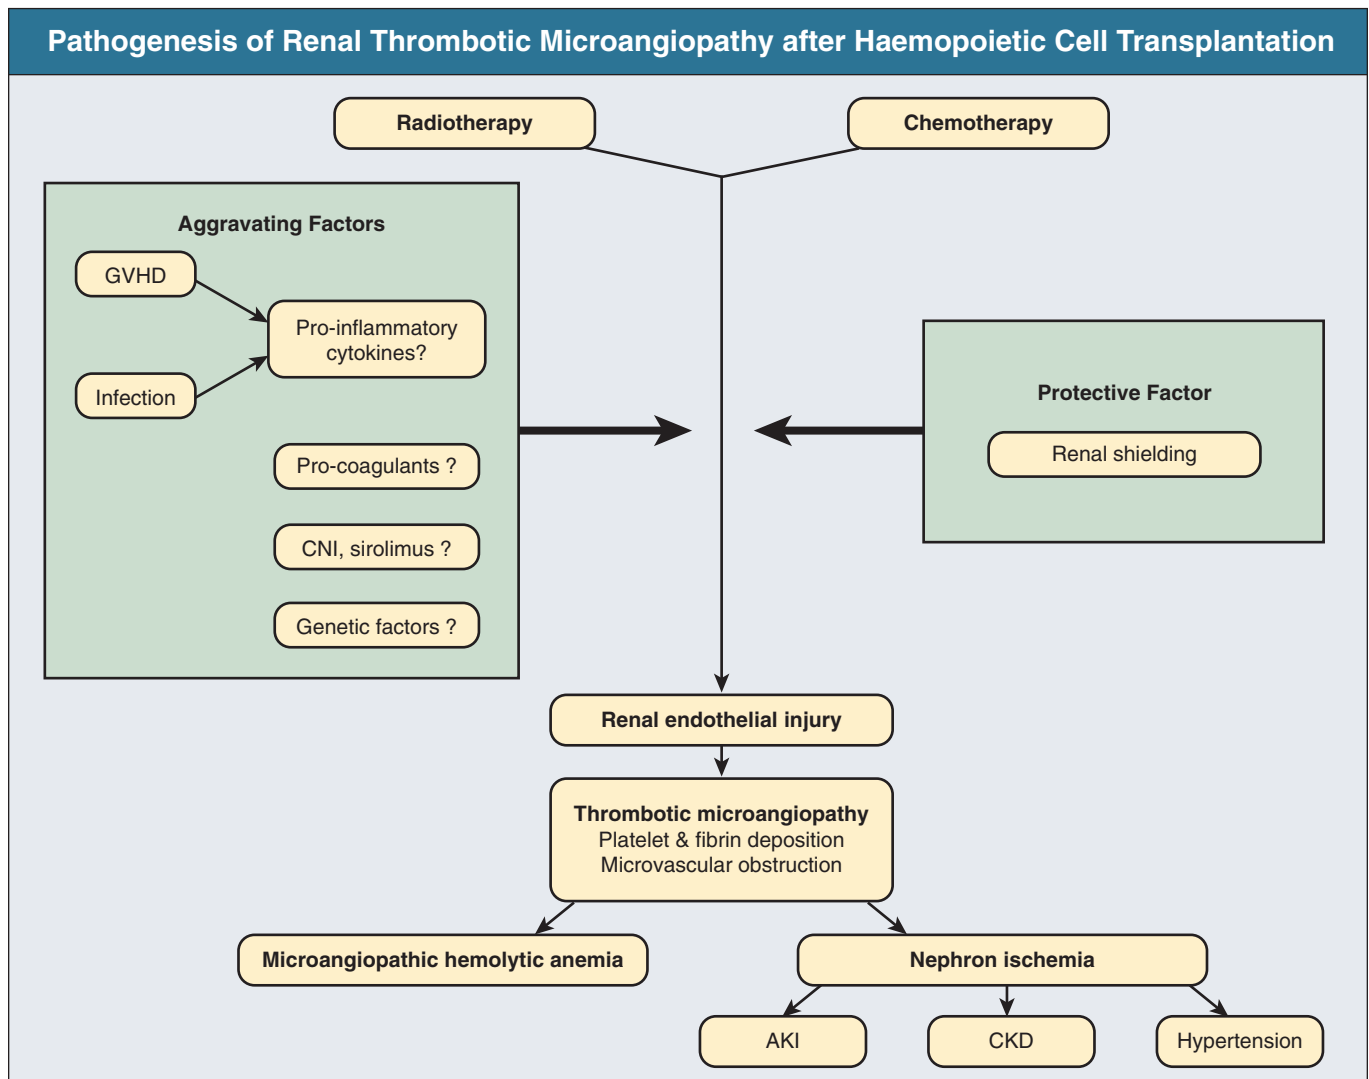

Figure 107.10 Proposed pathogenesis of renal thrombotic microangiopathy after haemopoietic cell transplantation. AKI, acute kidney injury; CKD, chronic kidney disease; CNI, calcineurin inhibitor; GVHD, graft-versus-host disease; TMA, thrombotic microangiopathy. (Modified from reference 36.)

to more immunosuppression. *De novo* membranous nephropathy is the most common biopsy finding; minimal change disease has also been reported. The original hematologic disease (such as myeloma) may also recur with renal involvement.

Management of Hematopoietic Cell Transplantation–Related Chronic Kidney Disease

Careful review of the patient's pre- and post-HCT history is essential. Attention should be paid to the following: type of HCT and conditioning regimen (in particular, whether total body irradiation was used and at what dose) and degree of exposure to nephrotoxins. The examination frequently shows hypertension, hypervolemia, and skin GVHD. Blood test results should be reviewed carefully and tests repeated to assess for TMA; the laboratory features of TMA are often intermittent and not florid. Urine dipstick findings of hematuria and moderate proteinuria are suggestive of renal TMA but of course are not specific to this condition. Renal ultrasound is often used to exclude postrenal causes, but other imaging studies are usually unnecessary. As discussed before, kidney biopsy is rarely indicated.

General treatment should be as recommended for any patient with CKD. Aggressive control of hypertension is warranted. For the patient with TMA, plasma exchange does not appear to be beneficial.^{37,44} RAS blockade slows progression in animal models of radiation nephropathy and is recommended for this reason and also for its beneficial effects in hypertensive proteinuric CKD.³³ CNI doses should probably be minimized if this is thought "safe" for the management of the HCT. Substitution of CNIs by interleukin-2 receptor blockers in the setting of GVHD and renal dysfunction might improve renal function but remains experimental at this time.⁴⁵

A subset of patients will progress to ESRD, and overall, these patients have worse survival on dialysis than non-HCT controls do.⁴⁶ Suitability for renal transplantation should be carefully judged on a case-by-case basis. On occasion, the allogeneic stem cell donor can donate a kidney; a great benefit of this approach is that a state of tolerance to the allograft should exist, and hence minimal or no immunosuppression is required.⁴⁷ If this option is not available and the patient receives a conventional kidney transplant, low-dose immunosuppression should be prescribed as HCT recipients may not have normal immunity and remain at higher risk of infection.⁴⁷
